Monopsony and the Wage Effects of Migration

Michael Amior
Alan Manning
Abstract
In a competitive labor market, immigration affects native wages only through its impact on marginal products. Under the sole assumption of constant returns, we show that a larger supply of migrants (keeping their skill mix constant) must increase the marginal products of native-owned factors on average (an extension of the familiar “immigration surplus” result); and in the long run (if capital is supplied elastically), this surplus passes entirely to native labor. However, in a monopsonistic labor market, wages will also depend on any mark-downs applied by firms; and immigration may affect native wages through these mark-downs. We present a model of monopsony which generates testable restrictions on the null hypothesis of perfect competition, which we reject using US census data commonly studied in the literature. Our estimates suggest that the (negative) mark-down effect dominates the (by construction, positive) effect on marginal products for the average native. These findings shed new light on the interpretation of previous empirical estimates and the so-called “structural approach” to predicting wage effects.

Key words: Migration, wages, monopsony

1 Introduction

Much has been written on the impact of migration on native wages: see, for example, recent surveys by Borjas (2014), Card and Peri (2016) and Dustmann, Schoenberg and Stuhler (2016). This literature has traditionally studied these effects through the lens of a competitive labor market, where wages are equal to the marginal products of labor. In this paper, we assess the implications and robustness of this assumption.

We make three contributions to the literature. First, we offer new results on how immigration affects natives’ marginal products. Under the sole assumption of constant returns, we show a larger supply of migrants (keeping their skill mix constant) must always increase the marginal products of native-owned factors on average (in a closed economy), as long as native and migrant workers have different skill mixes; and in the long run (if capital is supplied elastically), this surplus passes entirely to native labor. Borjas (1995) famously proved this “immigration surplus” result for a one-good economy with up to two types of labor and capital; but we demonstrate it holds for any number of labor types, any number of (intermediate or final) goods, and any form of technology, as long as there are constant returns to scale. This does not mean that the marginal products of all native workers will increase: there may be large distributional effects. Although these are theoretical results, they do have empirical implications: any empirical model which imposes constant returns and perfect competition (as all existing “structural models” do, e.g. Borjas, Freeman and Katz, 1997; Borjas, 2003; Card, 2009; Manacorda, Manning and Wadsworth, 2012; Ottaviano and Peri, 2012) can only ever conclude that immigration (keeping the skill mix of migrants constant) increases the average native wage in the long run (where capital is elastic), whatever data is used for estimation.¹

Our second contribution is a theoretical and empirical model of the impact of immigration in the absence of perfect competition. In this environment, the wage of skill type $j$ natives will depend on both the marginal product and any mark-down $\phi_j$ imposed by monopsonistic firms:

$$\log W_j = \log MP_j - \phi_j$$

(1)

Just as there are good theoretical reasons to believe that natives’ marginal products are sensitive to immigration, our contention is that the same may be true of the mark-downs, if firms’ monopsony power depends on the labor share of migrants. In particular, if migrants supply labor to firms less elastically than natives (or migrants’ reservation wages are lower), firms can exploit immigration by imposing larger mark-downs on natives and migrants alike. We develop a theoretical, yet estimable, model to assess this possibility. There are a number of other papers which consider the impact of immigration in non-

¹Borjas (2013) also emphasizes that factor demand theory imposes strong constraints on the impact of migration on the average wage of all workers. Our contribution here is to develop the implications for natives specifically. He also considers extensions to open economies which we do not address here.
competitive settings: Chassamboulli and Palivos (2013, 2014), Chassamboulli and Peri (2015), Battisti et al. (2017), Albert (2017) and Amior (2017) offer theoretical discussions or calibrations of search or monopsonistic models; and Malchow-Moller, Munch and Skaksen (2012) and Edo (2015) offer suggestive evidence for mark-down effects. But as Borjas (2013) has noted, the literature is surprisingly sparse, given the ubiquity of imperfectly competitive models in other parts of labor economics.

There are a number of reasons why migrants may supply labor to firms less elastically (or have lower reservation wages). First, migrants may be less efficient in job search, due to lack of information, language barriers, exclusion from social networks or undocumented status (Hotchkiss and Quispe-Agnoli, 2013; Albert, 2017) or visa-related restrictions on labor mobility (see e.g. Depew, Norlander and Sørensen, 2017, on the H1B). Second, migrants may discount their time in the host country more heavily, perhaps because they intend to only work there for a limited period (see Dustmann and Weiss, 2007), or there may be binding visa time limits or deportation risk. Third, migrants may face more restricted access to out-of-work benefits. Finally, migrants may base their reference points on their country of origin (Constant et al., 2017; Akay, Bargain and Zimmermann, 2017), whether for psychological reasons or because of remittances (Albert and Monras, 2018; Dustmann, Ku and Surovtseva, 2019). These intuitions are consistent with a range of empirical evidence: Hotchkiss and Quispe-Agnoli (2009), Hirsch and Jahn (2015) and Borjas (2017) confirm that migrants do indeed supply labor less elastically. Also, using a structural model, Nanos and Schluter (2014) find that migrants demand lower wages (for given productivity). And Dustmann, Ku and Surovtseva (2019) show that migrants’ reservation wages (and occupation quality) are sensitive to exchange rate fluctuations. Beyond this, the expenditures of individual employers on foreign recruitment (whether through political lobbying, payment of visa fees, or use of foreign employment agencies) offer prima facie evidence for a gap between migrants’ marginal products and their wages, suggestive of imperfect competition (Rodriguez, 2004; Fellini, Ferro and Fullin, 2007; Facchini, Mayda and Mishra, 2011).

But rather than relying on this literature, our third contribution is to directly test the claim that monopsony power depends on the migrant share - using standard wage and employment data from the US census, as analyzed (among others) by Borjas (2003) and Ottaviano and Peri (2012). We rely on a standard structural model with a nested CES technology (as in Ottaviano and Peri, 2012 or Manacorda, Manning and Wadsworth, 2012), but we relax the assumption of perfect competition. Wages of each labor type de-

\[2\] Using Danish data, Malchow-Moller, Munch and Skaksen (2012) find that migrant employees depress native wages within firms; and they cite lower reservation wages as a possible explanation. Edo (2015) finds that non-nationalized migrants in France reduce native employment rates, while naturalized migrants have no effect; and he too relates this to reservation wages. Also, Naidu, Nyarko and Wang (2016) study a UAE reform which relaxed restrictions on employer transitions for migrant workers (and improved their outside options), though they focus on the implications for incumbent migrants rather than natives.
pend on both the cell-specific marginal products and the cell-specific mark-downs, where cells are defined by education and experience. The marginal products are determined by the cell-level employment stocks, according to a functional form set by the technology. Conditional on these stocks, our model predicts that the mark-down effects are identified by the wage response to a cell’s composition (and specifically its migrant share). Our empirical strategy is closely related to Beaudry, Green and Sand (2012), who study the role of industrial composition in wage-setting under imperfect competition.3

Although the model is not fully identified, we are able to test (and reject) the null hypothesis that native and migrant mark-downs are equal and independent of the migrant share, of which perfect competition is a special case. For a native-migrant substitution elasticity similar to that of Ottaviano and Peri (2012), our estimates suggest a 1 pp increase in a cell’s migrant share allows firms to mark down native wages by 0.5-0.6% more; and the effect is similar for migrants. An analysis of alternative calibrations suggests this is a lower bound. This mark-down effect more than offsets the small (positive) surplus from changes in marginal products typically estimated by competitive structural models. The direction of the mark-down effect suggests that migrants do indeed supply labor to firms less elastically than natives. Consistent with this interpretation, we show that natives’ employment rates are more responsive to cell-specific wage changes (identified by immigration shocks) than those of migrants.

Our findings also shed new light on other debates in the empirical literature. A key source of contention is the appropriate functional form for migration shocks. While Borjas (2003 and 2014) uses the migrant share in the labor market cell, Peri and Sparber (2011) and Card and Peri (2016) argue this generates an artificial bias because of the endogeneity of the native labor supply (see e.g. Hunt, 2017; Llull, 2017) which appears in the share’s denominator, preferring instead a measure based on migrants’ contribution to the size of the cell. In our model, there is a role both for the size of the cell (which determines the impact on marginal products) and the mix of the cell (i.e. the migrant share), which accounts for the extent of labor market competition within the cell. We attempt to address the empirical concerns by introducing instruments for native and migrant labor supply, based on education cohort sizes at the previous observation both at home (for US residents) and abroad (for new immigrants). See also Llull (2018) and Monras (forthcoming) for earlier attempts to instrument for cell-specific immigration.

Given the apparent fragility of the competitive markets assumption, one may choose to abandon structural approaches to estimating wage effects altogether - in favor of more empirical reduced-form strategies. Dustmann, Schoenberg and Stuhler (2016) recommend this strategy, though for different reasons, namely the difficulty of correctly allocating migrants to skill cells (if migrants do not compete with equally skilled natives). But, there

3They show that wage bargains (for given productivity) depend on local industrial composition, since this affects workers’ outside options. In our paper, it is the composition of the labor force which matters.
are advantages to the structural approach: reduced form studies typically cannot estimate the impact of different types of migrants on different types of natives. If there are \( A \) native types and \( B \) migrant types, one would need to include \( A \times B \) interactions in a fully specified reduced-form model, almost certainly more than can be estimated from the data. In practice, the reduced-form approach is typically restricted to studying the impact of particular migration events, which bring particular skill mixes. Though natural experiments may offer remarkably clean identification (see e.g. Dustmann, Schoenberg and Stuhler, 2017; Edo, forthcoming; Monras, forthcoming), it may be difficult to extrapolate to other scenarios. Instead, our paper offers an approach to embedding more flexible assumptions on labor market competition within a tractable structural framework.

Our mark-down results may be interpreted as supporting a story of “cheap” migrant labor undercutting native wages, which often has strong resonance in the public consciousness.\(^4\) However, it is important to note that such effects may be offset through policies which constrain monopsony power (such as minimum wages: see Edo and Rapoport, 2017, for evidence), rather than by restricting migration itself. In fact, these objectives may come into conflict: for example, limitations on migrant access to welfare benefits or visa restrictions (designed to deter migration) may deliver more market power to firms, and natives may ultimately suffer (Amior, 2017).

In the next section, we set out our theoretical results on the effects of immigration on marginal products, under the assumptions of constant returns. Section 3 extends our framework to allow for monopsonistic firms. In Section 4, we describe our data, which are based on the classic studies of Borjas (2003) and Ottaviano and Peri (2012); and we then turn to identification and our empirical strategy in Section 5. Section 6 presents our basic estimates, and we offer various empirical extensions in Section 7.

## 2 Immigration surplus results: Impact on natives’ marginal products

In a competitive labor market, the wages of native labor are fully determined by their marginal products (MPs). In this section, we offer a set of “immigration surplus” results which describe how immigration affects these MPs in a closed economy.\(^5\) Underpinning our results is the crucial assumption of constant returns to scale (CRS).

\(^4\)One representative example from Bernie Sanders: “Bringing undocumented workers out of the shadows will make it more difficult for employers to undercut the wages and benefits of all workers” (\emph{Sunday Express}, 11/02/2016, “Bernie Sanders for President? Policy on ISIS, immigration and abortion”).

\(^5\)See Borjas (2013) for an open economy model, which shows the wage effects of immigration will depend on the extent to which natives and migrants consume imported goods.
Consider the following production function:

\[ Y = F(K, L) \]  

where \( K = (K_1, K_2, \ldots, K_I) \) is a vector of perfectly elastic factor inputs, and \( L = (L_1, L_2, \ldots, L_J) \) is a vector of inputs which are treated as fixed (either because they are inelastically supplied, or simply for analytical convenience). Each input may be owned by native or migrants, or a combination of the two. Without loss of generality, we identify the fixed inputs with labor and the elastic ones with capital (or non-labor factors more generally). This approach follows the precedent of the migration literature, which traditionally equates an elastic supply of capital with a “long run” scenario. We consider more general scenarios at the end of this section, as well as the case of factor inputs in imperfectly elastic supply.

Under the assumption of CRS, we can simplify the analysis with the following claim:

**Proposition 1.** We can summarize total revenue net of the costs of the (elastic) \( K \) inputs using a “long run” production function \( \tilde{F}(L) \), where \( \tilde{F} \) has constant returns in the (fixed) \( L \) inputs, and where the derivatives of each \( L \) input equal their MPs.

**Proof.** See Appendix A, and see also Dustmann, Frattini and Preston (2012).

This proposition allows us to abstract away from the elastic “capital” inputs. In what follows, we will begin with the simplest possible model, and we will consider the implications for the immigration surplus as we progressively add more features.

### 2.1 Homogeneous natives and migrants

Suppose there are two fixed labor inputs, natives and migrants: \( L = (N, M) \); so long run output is \( \tilde{F}(N, M) \). Each group is homogeneous, though they may differ from each other. The two-input case was originally analyzed\(^6\) by Borjas (1995), but we summarize it here as it provides a useful foundation for more general results:

**Proposition 2.** Given CRS, a larger supply of homogeneous migrants \( M \) must strictly increase the MPs of homogeneous natives \( N \), unless natives and migrants are perfect substitutes - in which case there is no effect.

**Proof.** If there are two factor inputs with CRS, the inputs must be Q-complements: i.e. \( \tilde{F}_{NM}(N, M) \geq 0 \), where subscripts denote partial derivatives, and with equality only if \( N \) and \( M \) are perfect substitutes. It immediately follows that the MP of natives is increasing in migrant supply \( M \), unless the two inputs are perfect substitutes. \( \square \)

\(^6\)To be more precise, Borjas’ (1995) two inputs are capital and labor, where immigration contributes to the latter only. But the implications are the same.
2.2 Heterogeneous skills

Proposition 1 is well-known: see e.g. Borjas (2014, p. 65). But perhaps it is specific to the extreme case of two inputs. To investigate this, suppose there are \( J \) types of (fixed) labor inputs in the economy, characterized by arbitrary patterns of substitutability and complementarity. And for each labor type \( j \), suppose \( L_j = N_j + M_j \), where \( N_j \) and \( M_j \) are the native and migrant components respectively. Let \( \eta_j \equiv \frac{N_j}{N} \) denote the share of natives who are type-\( j \), and \( \mu_j \equiv \frac{M_j}{M} \) the type-\( j \) share of migrants. This set-up allows the possibility that any or all types are exclusively native or migrant, which would imply \( \eta_j \mu_j = 0 \) for some \( j \). Long run output (net of the elastic inputs’ costs) is then:

\[
\hat{Y} = \hat{F}(L_1, \ldots, L_J)
\]

And under the assumption of CRS, we can make the following claim:

**Proposition 3.** Suppose natives are divided into an arbitrary number of skill groups, and similarly for migrants. Given CRS, a larger supply of migrants \( M \) (holding their skill mix fixed) raises the average MP of natives, unless the skill mixes of natives and migrants are identical - in which case there is no effect.

**Proof.** Write the production function in (3) as:

\[
\hat{Y} = \hat{F}(\eta_1 N + \mu_1 M, \ldots, \eta_J N + \mu_J M) = Z(N, M)
\]

i.e. output can be expressed as a function \( Z \) of the total number of natives \( N \) and migrants \( M \), where the skill mix of these groups is subsumed in \( Z \). The function \( Z(N, M) \) must have CRS if \( \hat{F}(L_1, \ldots, L_J) \) does. And the partial derivative of \( Z(N, M) \) with respect to \( N \) can be written as:

\[
Z_N(N, M) = \sum_j \eta_j \hat{F}_j(L_1, \ldots, L_J)
\]

which is the average native MP (or, under perfect competition, the average native wage). Similarly, the partial derivative of \( Z(N, M) \) with respect to \( M \) is equal to the average migrant MP. In this way, we have reduced a production function with arbitrarily many types of labor to one with only two composite inputs, \( N \) and \( M \). Furthermore, \( Z \) satisfies the usual properties of production functions, with marginal products of the composite inputs equal to the average MP. And with two labor types and CRS, we already know (from Proposition 2) that an increase in the supply of one group (e.g. migrants) must increase the average MP of the other, as long as natives’ and migrants’ skill mixes differ. If the skill mixes are identical, then \( Z(N, M) = k(N + M) \) for some constant \( k \); and migration will have no effect on natives’ MPs, because they are effectively perfect substitutes (at the aggregate level).
Note that Proposition 3 applies only to the average native MP: there may be negative effects on particular skill types. For example, if all migrants were unskilled, a larger $M$ would compress the MPs of unskilled natives.

It is not entirely clear how well-known Proposition 3 is in the current literature. Dustmann, Frattini and Preston (2012) use a CES production function satisfying the requirements above and conclude: “For small levels of immigration, we should therefore expect to find mean native wages rising if capital is perfectly mobile. Indeed, there can be a positive surplus for labor if capital is mobile and immigrant labor sufficiently different to native labor [emphasis added]”. This result is similar to the one proved here, but we impose no restriction on technology beyond CRS (so a CES production function is not required), no requirement that immigration be “small”, and no requirement that native and migrant skill mixes be “sufficiently” different: we show that any difference will generate a surplus, though the size of the surplus will depend on the amount of immigration and the extent of skill differences between natives and migrants.

### 2.3 Changing the skill mix of immigration

Propositions 1-3 focus on how CRS constrains the response of natives’ MPs to immigration, holding the skill mix of migrants constant. However, CRS also constrains the possible response of natives’ MPs to changes in the skill mix of migrants. Denote the vector of natives’ skill shares ($\eta_1, \eta_2, \ldots, \eta_J$) by $\eta$, and suppose that the skill mix of migrants can be written as:

$$\mu(\zeta) = \eta + \zeta(\mu - \eta)$$

where $\zeta$ describes the extent to which the skill mixes of natives and migrants differ. If $\zeta = 0$, the two groups are identical, while $\zeta = 1$ corresponds to the case analyzed so far. It can then be shown that natives benefit from greater skill differences:

**Proposition 4.** An increase in $\zeta$ increases the average native MP.

**Proof.** See Appendix B.

Borjas (1995) makes a similar point, that the immigration surplus is increasing in native-migrant skill differences. But our result generalizes this claim to an economy with an arbitrary number of skill types.

### 2.4 Multiple goods

Until now, we have restricted attention to a single-good economy. But can allowing for multiple goods overturn the surplus result? In this more general environment, the marginal revenue products are affected by relative prices and not just technology. To obtain the welfare implications of immigration, we must therefore account for these price
changes; and this necessitates an assumption about price determination (which we did not require before). It turns out that if both product and labor markets are perfectly competitive, and if preferences are homothetic (so there is a single price index for all consumers, native and migrant alike), the surplus result continues to hold:

**Proposition 5.** In an economy with multiple (intermediate or final) goods, in which all sectors satisfy CRS, with perfect competition in all product and labor markets, and with all consumers having the same homothetic preferences, a larger supply of migrants (holding their skill mix constant) must increase the average utility of natives, unless the skill mixes of natives and migrants are identical (in which case there is no effect).

*Proof.* See Appendix C. □

Intuitively, one can think of all goods as being produced, directly or indirectly, by labor inputs. So, consumption of goods can be interpreted as demand for different types of labor. When $M$ increases, the relative price of goods which are intensive users of migrant labor (in the sense of supply minus demand) must fall, and this must be to the advantage of natives. Note that Proposition 4 also applies for the multiple good case.

### 2.5 Robustness of conclusions

To summarize, any model, theoretical or empirical, which imposes CRS and a perfectly elastic supply of capital (or non-labor) inputs, must always predict that more immigration (holding migrants’ skill mix constant) weakly increases native labor’s average MP in a closed economy, irrespective of the data used for estimation.

We have assumed that the labor inputs in the $L$ vector are fixed, but allowing for an imperfect elasticity of labor supply would not change the nature of these results. It would still be the case that, holding the migrant skill mix fixed, immigration generates an outward-shift of the labor demand curve for the average native. Whether this shift manifests in higher wages or employment will depend on the elasticity of the supply of natives to the labor market. We return to this question in the empirical analysis below. But either way, the shift in MPs for fixed labor inputs is informative about whether market opportunities are improving for natives.

Above, we have identified the fixed inputs in $L$ with labor. But one may also consider “short run” scenarios where some capital inputs are fixed. In this more general case, the results above will apply to the average MP of all native-owned factors in the $L$ vector, whether labor or capital; and native labor may lose out on average. But to the extent that capital (and other non-labor) inputs become elastic in the “long run”, the entire surplus will ultimately pass to native labor. Certainly, there are various objections to this long run scenario: persistent immigration may depress wages if capital cannot accumulate fast enough (Borjas, 2019), though immigration may also generate increasing returns if there
are human capital externalities. Nevertheless, Ottaviano and Peri (2008) argue that long run macroeconomic trends are consistent with CRS and elastic capital.

In a competitive labor market, the predicted increase in native labor’s average MP will necessarily translate to larger average wages. However, we now show that an imperfectly competitive model does admit the possibility of negative wage effects (even if MPs increase), if immigration increases the monopsony power of firms.

3 Modeling imperfect competition

3.1 Existing literature

There is a small existing literature which models the impact of migration under imperfect competition. The earliest studies (Chassamboulli and Palivos, 2013, 2014; Chassamboulli and Peri, 2015; Battisti et al., 2017) assume wages are bargained individually (due to random matching), which rules out direct competition between natives and migrants. As a result, natives unambiguously benefit from low migrant reservation wages: immigration stimulates the creation of new vacancies, which improves natives’ outside options and wage bargains. In contrast, Albert (2017) and Amior (2017) do allow for direct competition; but both assume marginal products are fixed, which rules out wage effects through traditional competitive channels. We offer a simple framework which accounts for both.

3.2 Imperfect competition and mark-downs

We account for imperfect competition by modeling wage mark-downs. Based on (1) in the introduction, we summarize the wage of type $j$ workers as:

$$\log W_j = \log \hat{F}_j - \phi_j$$  \hfill (7)

where $\hat{F}_j$ is the marginal product (for long run output), and $\phi_j \geq 0$ is the mark-down, equal to zero in a perfectly competitive market. In what follows, we interpret the mark-downs as arising from a simple monopsony model (as used by Card et al., 2018), where the market power of wage-setting firms depends on the elasticity of labor supply they individually face. But a wage equation like (7) may alternatively be derived from a bargaining model (see e.g. Barnichon and Zylberberg, 2019, for an exposition where matching is not entirely random), where wages depend on marginal products, reservation wages and workers’ bargaining power.

We define the markets for each labor type $j$ sufficiently narrowly, such that all constituent natives and migrants are perfect substitutes and receive the market wage $W_j$.  

---

7 This builds on the ideas of Albrecht and Axell (1984) and Burdett and Mortensen (1998), who study the equilibrium labor market implications of heterogeneous leisure values.
The allocation of natives and migrants across these markets may differ (according to the \( \eta \) and \( \mu \) vectors defined above), whether because of divergent productive specializations (e.g. Peri and Sparber, 2009, emphasize comparative advantage in communication or manual tasks) or labor market discrimination. We do not permit discrimination within markets; but this should not be restrictive, if they are defined sufficiently narrowly. The market wage is determined by the standard monopsony formula, \( W_j = \frac{\epsilon_j}{1+\epsilon_j} F_j \), where \( \epsilon_j \) is the elasticity of labor supply to individual firms (rather than to the market as a whole). Consequently, the mark-down \( \phi_j \) in (7) can be expressed as:

\[
\phi_j = \log \left( 1 + \epsilon_j^{-1} \right)
\]  

(8)

where \( \epsilon_j \) is a weighted average of the elasticities of native and migrant labor supply to firms (denoted \( \epsilon_N \) and \( \epsilon_M \) respectively), with the weight depending on the migrant share in market \( j \):

\[
\epsilon_j = \epsilon_N + \frac{\mu_j M}{\mu_j M + \eta_j N} (\epsilon_M - \epsilon_N)
\]  

(9)

and where \( \mu_j \) and \( \eta_j \) are the shares of migrants and natives allocated to market \( j \).

### 3.3 Aggregation

Our analysis above applies to markets \( j \) which are sufficiently narrow such that all constituent natives and migrants are perfect substitutes. In practice, we assume we cannot observe these “true” markets; instead simply observing an aggregate of them. However, Proposition 3 allows us to model this aggregate: we combine the output of the individual markets \( j \) using a CRS function \( Z(N, M) \), which subsumes the submarket allocations \( \eta \) and \( \mu \), and which depends solely on the total native and migrant stocks. Our approach here builds on an existing literature on such aggregations in the production function and growth literature (Houthakker, 1955; Levhari, 1968; Jones, 2005; Growiec, 2008). As we show in Appendix D, the average native and migrant wage can be written as:

\[
\log W_N = \log Z_N - \phi_N \left( \frac{M}{N} \right)
\]  

(10)

\[
\log W_M = \log Z_M - \phi_M \left( \frac{M}{N} \right)
\]  

(11)

where \( Z_N \) and \( Z_M \) are the average native and migrant MPs, and \( \phi_N \) and \( \phi_M \) are the aggregated native and migrant mark-downs. Note that \( \phi_N \) and \( \phi_M \) will differ if natives and migrants are allocated differently across unobserved submarkets, in which case each are distinct functions of the migrant share.

Our interpretation of \( Z \) as an *aggregation* of many markets is important to our specification. Suppose instead that the \( N \) and \( M \) arguments of \( Z(N, M) \) represent two distinct
skill inputs. Firms would then set distinct wages for each input, so natives would be sheltered from any direct competition from migrants (beyond any effect migrants may have on their marginal products). This would rule out any effect of immigration on mark-downs, even if firms had market power. Direct competition would only arise in the extreme case where natives and migrants are perfect substitutes and therefore compete in the same market. In contrast, our aggregation approach allows imperfect competition to coexist with direct competition at the level of observed labor markets.

In (10) and (11), we interpret $Z$ as aggregate output, and $W_N$ and $W_M$ as national average wages. But $Z$ may equally represent any observable nest of a multi-level production function. For example, in our empirical application below, we interpret $Z$ as an education-experience cell; so $W_N$ and $W_M$ represent mean wages within those cells. The idea that these cells may aggregate the outputs of unobserved markets builds on Dustmann, Schoenberg and Stuhler (2016).

### 3.4 Impact of immigration on aggregate mark-downs

We wish to know how immigration affects the aggregate mark-downs, $\phi_N$ and $\phi_M$. These effects are largely determined by the differential between the native and migrant elasticities, $\epsilon_N$ and $\epsilon_M$. To illustrate this point, we now work intuitively through some cases of interest. We refer readers to Appendix D for a more formal exposition.

Consider first the case where natives and migrants supply labor to firms with equal elasticities, i.e. $\epsilon_M = \epsilon_N$. Based on (9), the overall elasticities $\epsilon_j$ are then independent of migrant share and invariant with submarket $j$. And so, natives will face the same mark-downs as migrants ($\phi_N = \phi_M$); and both will be independent of migrant share. We illustrate $\phi_N$ and $\phi_M$ as functions of migrant share in Figure 1a. In the empirical analysis, we will treat this case (of equal and independent mark-downs) as our null hypothesis. This environment is implicitly assumed by the seminal studies in the literature: mark-downs are fixed constants, and immigration only affects wages through marginal products. Note that perfect competition is a special case of $\epsilon_M = \epsilon_N$, where both $\epsilon_M$ and $\epsilon_N$ are infinite, and both $\phi_N$ and $\phi_M$ equal zero, irrespective of migrant share.

In Figure 1b, we consider the case where migrants supply labor less elastically to firms ($\epsilon_M < \epsilon_N$), as the evidence detailed in the introduction might suggest. Migrants must, on average, be in submarkets $j$ with larger migrant shares and larger mark-downs; and therefore, $\phi_M \geq \phi_N$. However, $\phi_M$ and $\phi_N$ must converge to equality as $\frac{M}{N} \to 0$ or $\frac{M}{N} \to \infty$. Intuitively, as the labor force becomes exclusively native or migrant, the

---

\*\*In this case, we would also need to account for the marginal contribution of the nest $Z$ to aggregate output in (10) and (11). \*\*
elasticity facing firms converges to the native or migrant one, in which case all workers will face the same mark-down. Also, both $\phi_N$ and $\phi_M$ must be increasing in $M_N$, as firms can exploit the less elastic supply of migrants by cutting wages. And given the equality of $\phi_M$ and $\phi_N$ in the limits, the differential between $\phi_M$ and $\phi_N$ must be non-monotonic in $M_N$. The final case, $\epsilon_M > \epsilon_N$, is of course the reverse of $\epsilon_M < \epsilon_N$, given the symmetry of the model.

The response of the mark-downs $\phi_N$ and $\phi_M$ to migrant share will depend on the extent of labor market segregation, i.e. the deviation between the native and migrant skill mixes, $\eta$ and $\mu$. Greater segregation will moderate the impact of immigration, as the submarket migrant shares become less responsive to the aggregate-level migrant supply $M$. This offers an interesting counterpoint to the impact of immigration on the average native MP, which is increasing in the extent of segregation (see Proposition 4).

To summarize, for the average native, the effect of immigration on mark-downs may in principle offset its (positive) effect on marginal products. We have offered one story for the relationship between the mark-downs and migrant share (in terms of differential elasticities), but there may be others - and we do not rule these out. In what follows, we consider the estimation of these mark-down effects in practice. These estimates have validity even if the source of the mark-downs differs from that proposed here. We first discuss the data we use for estimation, and we then turn to our empirical methodology.

4 Data

4.1 Samples and variable definitions

We have chosen to describe our data at this stage, so as not to interrupt the discussion later on. Similarly to Borjas (2003; 2014) and Ottaviano and Peri (2012), we will study how wages respond to native and migrant employment stocks, exploiting variation across education-experience groups and US census years. But we will offer a different interpretation of these estimates, based on our monopsony model - as we explain below.

We construct our data in a similar way to these earlier studies, but we extend the time horizon: we use IPUMS (Ruggles et al., 2017) census extracts of 1960, 1970, 1980, 1990 and 2000, and American Community Survey (ACS) samples of 2010 and 2017.\footnote{The 1960 census does not report migrants’ year of arrival, but we require this information to construct our instruments, as well as for particular empirical specifications. In particular, we need to know the employment stocks of migrants living in the US for no more than ten years. We impute these stocks using education cohort sizes by country of origin in 1950, combined with origin-specific data on employment rates. See Appendix F for further details.}

Throughout, we exclude under-18s and those living in group quarters. Following Borjas (2003) and Ottaviano and Peri (2012), we group individuals into

\footnote{In Appendix D, we summarize the differential between $\phi_M$ and $\phi_N$ as the covariance between submarket migrant allocations and submarket mark-downs.}
four education groups in our main specifications: (i) high school dropouts, (ii) high school graduates, (iii) some college education and (iv) college graduates. But we also consider specifications with two groups, college and high-school equivalents. Following Borjas (2003; 2014) and Ottaviano and Peri (2012), we divide each education group into eight categories of potential labor market experience, based on 5-year intervals between 1 and 40 years - though we also estimate specifications with four 10-year categories. To predict experience, we assume high school dropouts begin work at 17, high school graduates at 19, those with “some college” at 21, and college graduates at 23.

We identify employment stocks with hours worked by demographic cell, and wages with log weekly earnings of full-time workers (at least 35 weekly hours and 40 weeks per year), weighted by weeks worked - though we study robustness to using hourly wages. Following the recommendation of Borjas (2003 and 2014), we exclude enrolled students from the wage sample.

### 4.2 Composition-adjusted wages

Ruist (2013) argues that Ottaviano and Peri’s (2012) estimates of the elasticity of relative migrant-native wages (within education-experience cells) may be conflated with changes in the composition of the migrant workforce (by country of origin). To address this issue (and related concerns about composition effects), we adjust wages for observable changes in demographic composition over time in some specifications.

We begin by pooling census and ACS microdata from all our observation years. Separately for each of our 32 education-experience cells, and separately for men and women, we regress log wages on a quadratic in age, a postgraduate education indicator (for college graduate cells only), race indicators (Hispanic, Asian, black), and a full set of year effects. We then predict the mean male and female wage for each year, for a distribution of workers characteristics identical to the multi-year pooled sample (within education-experience cells). And finally, we compute a composition-adjusted native wage in each cell-year by taking weighted averages of the predicted male and female wages (using the gender ratios in the pooled sample as weights). We repeat the same exercise for migrants, but replacing the race indicators with 12 region of origin dummies in our regressions.

### 4.3 Instruments

An important concern is that both native and migrant employment stocks, by education-experience cell, may be endogenous to wages. Unobserved cell-specific demand shocks

---

11 Borjas (2014) further divides college graduates into undergraduate and postgraduate degree-holders. We choose not to account for this distinction, as there are very few postgraduates early in our sample.

12 Specifically: North America, Mexico, Other Central America, South America, Western Europe, Eastern Europe and former USSR, Middle East and North Africa, Sub-Saharan Africa, South Asia, Southeast Asia, East Asia, Oceania.
may affect the labor supply or human capital choices of both natives (Hunt, 2017; Llull, 2017) and foreign-born residents, as well as the skill mix of new migrants from abroad (Llull, 2018; Monras, forthcoming). We use instruments to predict employment stocks (by demographic cell) for each of three worker types: (i) natives, (ii) “old” migrants (living in the US for more than ten years) and (iii) “new” migrants (no more than ten years).

Our instrument for native employment is based on cohort sizes and education choices ten years earlier. For individuals aged over 33, we predict current employment using the ten-year lagged native employment stock (within education groups), separately by single-year age. This is not feasible for 18-33s: given our assumptions on graduation dates, some of them will not have reached their final education status. For this group, we begin with the ten-year lagged total cohort size (again, separately by single-year age); and we allocate these individuals to education groups using the education shares (also lagged ten years) of the cohort which is ten years older. Having predicted population stocks by single-year age and education, we then aggregate to 5-year experience groups. And we then linearly project the log native employment stock (across cells and years) on the log predicted population. The predicted employment stock, $\tilde{N}_{ext}$, then serves as our instrument. We construct our instrument for “old” migrants, $\tilde{M}_{old ext}$, in an identical way.

Analogously to our approach for existing US residents, we predict “new” migrant inflows using lagged cohort sizes in origin countries. This is motivated by Hanson, Liu and McIntosh (2017), who relate the rise and fall of US low skilled immigration to changing fertility patterns in Latin America. We are also building on Llull (2018) and Monras (forthcoming), who offer alternative instruments for cell-specific inflows of new migrants: Monras exploits a natural experiment (the Mexican Peso crisis), while Llull bases his instrument on interactions of origin-specific push factors, distance and skill-cell dummies. But for consistency with our approach for existing residents, we instead exploit data on lagged population stocks.

We predict cell-specific inflows using estimates from the following regression:

$$\log M_{new}^{ext} = \lambda_0 + \lambda_1 \log (\text{OriginPop}_{oext-10}) + \lambda_2 Mobility_{ext} + OriginRegion_o + \varepsilon_{oext}$$

where our dependent variable, $M_{new}^{ext}$, is the US employment stock of new migrants (with up to ten years in the US) at each observation year $t$ (between 1960 and 2017), for each of 164 origin countries $o$ and 32 education-experience cells $(e, x)$. We take this information from our ACS and census samples. $\text{OriginPop}_{oext-10}$ is the population of the relevant education cohort at origin $o$ ten years before $t$, which we take from Barro and Lee (2013) and the UN World Population Prospects database.13 We assign cohorts aged 18-33 to

---

13The Barro-Lee data offer population counts by country, education and 5-year age category for individuals aged 15 or over. We identify Barro and Lee’s “complete tertiary” education category with college graduates, “incomplete tertiary” with some college, “secondary complete” with high school graduates,
education groups in the same way as for US natives, based on the education choices of
the previous cohort at origin. For a given cohort size, one would of course expect more
emigration among more mobile demographic groups - especially the young. To account
for this, we also include a cell-specific measure of mobility, $Mobility_{ext}$, equal to the cross-
state migration rate$^{14}$ within the US in 1960. And finally, we control for a set of 12 region
of origin effects (see footnote 12), which account for the fact that demographic shifts in
certain regions matter more for migratory flows to the US.

Using our predicted values for log $M_{new}^{ext}$, we then impute total inflows by education-
experience cell $(e, x)$ for the ten years before each observation year $t$, by taking exponents
and summing over origin countries $o$. We denote this predicted employment stock of new
migrants as $\tilde{M}_{new}^{ext}$. Effectively, this is a weighted average of lagged cohort sizes in origin
countries, where the weights depend on origin-specific migration propensities and cell-
specific mobility. And we can now predict the total migrant stock as $\tilde{M}_{ext} = \tilde{M}_{old}^{ext} + \tilde{M}_{new}^{ext}$.

4.4 Descriptive statistics

Table 1 sets out a range of descriptive statistics, across our 32 education-experience cells.
All wage data in the table is adjusted for changes in demographic composition, and we
have normalized the wage changes in Panel C to have mean zero across all groups. The
average migrant employment share was just 5% in 1960 (Panel A), but reached 24% by
2017. This expansion was disproportionately driven by high school dropouts (Panel B).
Over the same period, native wages have declined most (in relative terms) among the
young and low educated (Panel C).

Panel D sets out the mean migrant-native wage differentials in each cell, averaged
over all sample years. In almost all cells, migrants earn less than natives, with wage
penalties varying from 0 to 15%, typically larger among high school workers and the
middle-aged. In the context of our model, these penalties may reflect differences in
within-cell marginal products or alternatively differential monopsony power. Either way,
this can be interpreted as “downgrading” (Dustmann, Schoenberg and Stuhler, 2016),
where migrants receive “lower returns to the same measured skills than natives”.

---

$^{14}$This is the share of natives in each demographic cell who lived in a different state 5 years previously.
5 Empirical model

We now turn to our empirical model. We begin by discussing identification of the markdown effects, and we then set out our estimation strategy. To make our model empirically tractable, we will impose particular functional forms. Our approach consists of two steps. First, we estimate a relative migrant-native wage equation; and we then use the parameters from this equation (plus some auxiliary assumptions) to estimate a native wage equation. This approach offers a simple way to test the assumption of zero markdown effects, which previous structural models in the literature have implicitly imposed.

5.1 Production technology and wages

Our empirical strategy is to exploit variation across education-experience cells, following a long-standing empirical literature beginning with Borjas (2003). We model these cells as the lowest (observable) level of a nested CES structure. In the long run, output $\hat{Y}_t$ at time $t$ (net of the elastic inputs’ costs) depends on the composite labor inputs, $L_{et}$, of education groups $e$:

$$\hat{Y}_t = \left( \sum_{e} \alpha_{et} L_{et}^{\sigma_e} \right)^{\frac{1}{\sigma_e}}$$

where the $\alpha_{et}$ are education-specific productivity shifters (which may vary with time), and $\frac{1}{1-\sigma}$ is the elasticity of substitution between education groups. In turn, the education inputs $L_{et}$ will depend on (education-specific) experience inputs $L_{ext}$:

$$L_{et} = \left( \sum_{x} \alpha_{ext} L_{ext}^{\sigma_x} \right)^{\frac{1}{\sigma_x}}$$

where the $\alpha_{ext}$ encapsulate the relative efficiency of the experience inputs within each education group $e$. Finally, in line with Card (2009), Manacorda, Manning and Wadsworth (2012) and Ottaviano and Peri (2012), we allow for distinct native and migrant labor inputs (within education-experience cells) which are imperfect substitutes:

$$L_{ext} = Z(N_{ext}, M_{ext})$$

We will ultimately impose a CES structure on $Z$ also; but for now, we assume only constant returns. As explained above, $Z$ can be interpreted as an aggregation of the outputs of many unobserved labor types or submarkets, which simultaneously permits both imperfect substitutability and direct competition between natives $N$ and migrants $M$. While equation (4) performs this transformation at the national level, we now perform it within education-experience cells.

We can then write equations for average native and migrant wages in education-
experience cells, based on (10) and (11):

\[
\log W_{\text{Next}} = A_{\text{ext}} \left[ Z \left( N_{\text{ext}}, M_{\text{ext}} \right) \right]^{\sigma_X - 1} Z_N \left( N_{\text{ext}}, M_{\text{ext}} \right) - \phi_N \left( \frac{M_{\text{ext}}}{N_{\text{ext}}} \right) \tag{16}
\]

\[
\log W_{M_{\text{ext}}} = A_{\text{ext}} \left[ Z \left( N_{\text{ext}}, M_{\text{ext}} \right) \right]^{\sigma_X - 1} Z_M \left( N_{\text{ext}}, M_{\text{ext}} \right) - \phi_M \left( \frac{M_{\text{ext}}}{N_{\text{ext}}} \right) \tag{17}
\]

The first term in each equation is the marginal product, and the second is the cell-level mark-down. We allow both the native and migrant mark-downs to depend (in possibly different ways) on the cell-level migrant composition, \( \frac{M_{\text{ext}}}{N_{\text{ext}}} \). Finally, \( A_{\text{ext}} \) is a cell-level productivity shifter:

\[
A_{\text{ext}} = \alpha_{\text{ext}} \left( \frac{\bar{Y}_t}{L_{\text{ext}}} \right)^{1-\sigma_E} L_{\text{ext}}^{1-\sigma_X} \tag{18}
\]

which summarizes the impact of all other labor market cells, as well as the general level of productivity.

### 5.2 Identification of mark-down effects

In principle, we would like to estimate the cell-level wage equations (16) and (17). However, it turns out we cannot separately identify (i) the cell aggregator \( Z \) in the lowest observable nest and (ii) the mark-down functions \( (\phi_N, \phi_M) \), using standard wage and employment data. Nevertheless, we can test the joint hypothesis that the native and migrant mark-downs are equal and independent of migrant share. This represents the case of equal elasticities \( (\epsilon_N = \epsilon_M) \) described in Figure 1a, of which perfect competition is a special case (where the mark-downs are equal to zero).

We begin by considering identification in the abstract, without imposing particular functional forms on \( Z, \phi_N \) and \( \phi_M \). Assuming the cell aggregator \( Z \) has constant returns, and suppressing the \( \text{ext} \) (education-experience-time) subscripts, it can be written as:

\[
Z \left( N, M \right) = Nz \left( \frac{M}{N} \right) \tag{19}
\]

for some single-argument function \( z \). Using (19), the wage equations (16) and (17) can then be expressed as:

\[
\log W_N = \log A - (1 - \sigma_X) \log N + \log \left[ \frac{z \left( \frac{M}{N} \right) - \frac{M}{N} z' \left( \frac{M}{N} \right)}{z \left( \frac{M}{N} \right)^{1-\sigma_X}} \right] - \phi_N \left( \frac{M}{N} \right) \tag{20}
\]

\[
\log W_M = \log A - (1 - \sigma_X) \log N + \log \left[ \frac{z' \left( \frac{M}{N} \right)}{z \left( \frac{M}{N} \right)^{1-\sigma_X}} \right] - \phi_M \left( \frac{M}{N} \right) \tag{21}
\]

where \( \sigma_X \) represents the substitutability between experience groups, and \( A \) is the cell-level productivity shifter defined by (18).
Clearly, it is impossible to separately identify a constant in \( A \) from one in the mark-downs, \( \phi_N \) and \( \phi_M \). Intuitively, the observed level of wages can be rationalized by one set of general productivity and mark-downs, but also by a higher level of productivity and larger mark-downs.\(^{15}\) One may be able to separately identify these parameters using data on output and labor shares, but we do not pursue this line of inquiry here.

Of greater concern for our purposes, we also cannot identify the relationship between the mark-downs and the migrant share, if this relationship is different for natives and migrants. To see this, suppose one observes a large number of labor markets, differing only in the total number of natives \( N \) and the ratio \( \frac{M}{N} \). Then, using (20) and (21), one can identify \( \sigma_X \) by observing how wages vary with \( N \), holding the ratio \( \frac{M}{N} \) constant (which fixes the final two terms in each equation). However, holding \( N \) constant and observing how wages vary with \( \frac{M}{N} \), it is not possible to separately identify the three functions \( (z, \phi_N, \phi_M) \), as we only have two equations.\(^{16}\)

But while the most general model is not identified, there are interesting models which can be estimated and tested. It is useful to consider two distinct hypotheses:

1. \( H_1 \) (Equal mark-downs): Natives face the same mark-downs as migrants within labor market cells, i.e. \( \phi_N \left( \frac{M}{N} \right) = \phi_M \left( \frac{M}{N} \right) \).

2. \( H_2 \) (Independent mark-downs): Natives’ mark-downs are independent of migrant share, i.e. \( \phi'_N \left( \frac{M}{N} \right) = 0 \).

Of course, \( H_1 \) and \( H_2 \) jointly imply that migrants’ mark-downs are also independent of migrant share, i.e. \( \phi'_M \left( \frac{M}{N} \right) = 0 \). In the model of Section 3, both \( H_1 \) and \( H_2 \) follow from the \( \epsilon_N = \epsilon_M \) case, where natives and migrants supply labor to firms with equal elasticities: see Figure 1a. But while we use the \( \epsilon_N = \epsilon_M \) case to motivate \( H_1 \) and \( H_2 \), our tests of these claims will have validity irrespective of the underlying theory of imperfect competition. Furthermore, for any theory, it will always be true that perfect competition is a special case of the joint hypothesis of \( H_1 \) and \( H_2 \), with both mark-downs equal to zero.

It turns out we can test this joint hypothesis: \( H_1 \) implies restrictions which make \( H_2 \) testable. Conditional on equal mark-downs (\( H_1 \)), the difference between (20) and (21) collapses to:

\[
\log \frac{W_M}{W_N} = \log \left[ \frac{z' \left( \frac{M}{N} \right)}{z \left( \frac{M}{N} \right) - \frac{M}{N} z' \left( \frac{M}{N} \right)} \right] \tag{22}
\]

\(^{15}\)There may also be a mark-up if there is imperfect competition in the product market. Any such mark-up is unlikely to depend on the migrant share in the workforce, so we subsume this in the constant.

\(^{16}\)Identification may be feasible as \( \frac{M}{N} \to 0 \) or \( \frac{M}{N} \to \infty \), if one accepts our micro-foundation for the mark-downs. As we argue in Section 3.4, the difference between \( \phi_N \) and \( \phi_M \) must converge to 0 at the limits. So, taking differences between (20) and (21), we can identify \( Z \) (at least at the limits); and given \( Z \), we can back out the mark-down functions. However, we do not pursue this strategy: “identification at infinity” may be feasible asymptotically, but it will be unreliable in small samples.
Using (22), variation in $\frac{M}{N}$ can then identify $z \left( \frac{M}{N} \right)$ up to a constant. And with knowledge of $z$, we can identify the native mark-down $\phi_N \left( \frac{M}{N} \right)$ up to a constant, using (20). Intuitively, knowledge of $z \left( \frac{M}{N} \right)$ allows us to predict how the native marginal product varies with $\frac{M}{N}$; so we can attribute the remaining effect of $\frac{M}{N}$ on wages to the mark-down (conditional on native employment $N$, which identifies the substitutability $\sigma_X$ between experience groups). So conditional on equal mark-downs ($H1$), we are able to test whether the native mark-down is independent of the migrant share ($H2$). A rejection of $H2$ would then imply rejection of the combination of $H1$ and $H2$ (i.e. the null hypothesis of equal and independent mark-downs), of which perfect competition is a special case.

5.3 Empirical specification

Above, we have considered identification in the abstract; and we now turn to estimation and testing in practice. To this end, we impose more structure on the technology and mark-down functions. Assume $Z$ has CES form:

$$Z (N, M) = (N^{\sigma_Z} + \alpha_Z M^{\sigma_Z})^{1 \over \sigma_Z} \quad (23)$$

where $\alpha_Z$ is a migrant-specific productivity shifter, and $\frac{1}{1-\sigma_Z}$ is the elasticity of substitution between natives and migrants (within education-experience cells). From this, it follows that:

$$z \left( \frac{M}{N} \right) = \left[ 1 + \alpha_Z \left( \frac{M}{N} \right)^{\sigma_Z} \right]^{1 \over \sigma_Z} \quad (24)$$

And suppose we approximate the mark-downs $\phi_N$ and $\phi_M$ by log-linear functions of $\frac{M}{N}$:

$$\phi_N \left( \frac{M}{N} \right) = \phi_{0N} + \phi_{1N} \log \frac{M}{N} \quad (25)$$
$$\phi_M \left( \frac{M}{N} \right) = \phi_{0N} + \Delta \phi_0 + (\phi_{1N} + \Delta \phi_1) \log \frac{M}{N} \quad (26)$$

where we permit the two mark-downs to have different intercepts and different sensitivity to $\frac{M}{N}$. Note that equal mark-downs ($H1$) would imply $\Delta \phi_0 = \Delta \phi_1 = 0$, and independence of the native mark-down ($H2$) would imply $\phi_{1N} = 0$. Though we express the mark-downs as functions of $\log \frac{M}{N}$, there are good theoretical reasons to prefer a specification in terms of the migrant share, $\frac{M}{N+M}$: equal absolute changes are more likely to have the same impact on mark-downs than equal proportionate changes. We make this point more formally in Appendix E. But as we now show, we can better illustrate the identification problem by formulating (25) and (26) in terms of $\log \frac{M}{N}$.

Applying (24)-(26) to (20) and (21) respectively, and taking differences, yields the
following expression for log relative wages:

\[
\log \frac{W_M}{W_N} = \log \alpha_Z - \Delta \phi_0 - (1 - \sigma_Z + \Delta \phi_1) \log \frac{M}{N}
\]  

Equation (27) illustrates the identification problem: the intercept of the relative wage equation only allows us to estimate \((\log \alpha_Z - \Delta \phi_0)\), and the slope coefficient \(- (1 - \sigma_Z + \Delta \phi_1)\).\(^{17}\) Manacorda, Manning and Wadsworth (2012) and Ottaviano and Peri (2012) implicitly solve this problem by assuming equal mark-downs \((H1)\), i.e. \(\Delta \phi_0 = \Delta \phi_1 = 0\). Though we cannot test \(H1\) in isolation, as we have explained above, we are able to test the joint hypothesis of \(H1\) and \(H2\).

In practice, our strategy is the following. Under the assumption of equal mark-downs \((H1)\), we identify \(\alpha_Z\) and \(\sigma_Z\) using the relative wage equation (27). Using (20), (24) and (25), the native wage can then be written as:

\[
\log W_N + (1 - \sigma_Z) \log N = \log A - \phi_{0N} - (\sigma_Z - \sigma_X) \log (N^{\sigma_Z} + \alpha_Z M^{\sigma_Z})^{\frac{\sigma_Z}{\sigma_Z + 1}} - \phi_{1N} \log \frac{M}{N}
\]  

The left-hand side of (28) is a weighted average of log native wages and employment. This has precedent in the literature on skill-biased technical change: see e.g. Berman, Bound and Griliches (1994). If, for example, the production nest \(Z\) is Cobb-Douglas (so \(\sigma_Z = 0\)), the left-hand side is the total log wage bill accruing to natives.

Given our estimates of \((\alpha_Z, \sigma_Z)\), we can then regress \([\log W_N + (1 - \sigma_Z) \log N]\) on \(\log (N^{\sigma_Z} + \alpha_Z M^{\sigma_Z})^{\frac{\sigma_Z}{\sigma_Z + 1}}\) and \(\log \frac{M}{N}\); and the estimated coefficient on \(\log \frac{M}{N}\) will identify \(\phi_{1N}\). Intuitively, the effect of immigration on the marginal products must enter through the cell “Armington” aggregator; so conditional on this, the cell composition \(\log \frac{M}{N}\) will pick up the mark-down effect. The hypothesis of independent native mark-downs \((H2)\) then yields a testable overidentifying restriction: that \(\phi_{1N} = 0\). We have framed this test using the native wage equation (28), but one may alternatively derive an equivalent equation for migrant wages. However, this would add no information beyond the combination of the relative wage equation (27) and the native levels equation (28).

6 Estimates of wage effects

We now turn to our empirical estimates. We begin by estimating the relative wage equation (27). On imposing \(H1\), we are able to identify \((\alpha_Z, \sigma_Z)\), and this allows us to test the joint hypothesis of \(H1\) and \(H2\) by estimating the native wage equation (28). As it happens, we reject this joint hypothesis; and we then explore set identification of the key parameters by exploiting the model’s various restrictions.

\(^{17}\)If we write (25) and (26) in terms of \(\frac{M}{N + M}\), we could in principle rely on functional form for identification. But we prefer not to pursue this strategy.
6.1 Estimates of relative wage equation

We initially parameterize the relative migrant productivity $\alpha_Z$ in (27) as:

$$\alpha_{Z\text{ext}} = \bar{\alpha}_Z + u_{\text{ext}} \quad (29)$$

for education $e$, experience $x$ and time $t$, where $\bar{\alpha}_Z$ is the mean across education-experience cells, and the deviations $u_{\text{ext}}$ have mean zero. (29) yields the following specification:

$$\log \frac{W_{M\text{ext}}}{W_{N\text{ext}}} = \beta_0 + \beta_1 \log \frac{M_{\text{ext}}}{N_{\text{ext}}} + u_{\text{ext}} \quad (30)$$

where $\beta_0$ identifies $\log \bar{\alpha}_Z - \Delta \phi_0$, and $\beta_1$ identifies $-(1 - \sigma_Z + \Delta \phi_1)$.

We report estimates of (30) in Table 2. In line with Ottaviano and Peri (2012), we cluster our standard errors by the 32 education-experience groups. And following the recommendation of Cameron and Miller (2015), we apply a small-sample correction to the cluster-robust standard errors (in this case, scaling them by $\sqrt{G(G-1)N^{N-K}}$) and using $T(G-1)$ critical values, where $G$ is the number of clusters, and $K$ the number of regressors and fixed effects. We apply these adjustments both for OLS and IV. The relevant 95% critical value of the $T$ distribution (with 31 degrees of freedom) is 2.04.\footnote{As Cameron and Miller (2015) emphasize, these adjustments do not entirely eliminate the bias. But even when we reduce the number of clusters to 16 (see below), bootstrapped estimates suggest the bias is small in this data: see Section 7.2.}

In column 1, we present OLS estimates for “raw” wages (i.e. not adjusted for changes in demographic composition): $\beta_0$ takes a value of -0.14, and $\beta_1$ is -0.033. These numbers are comparable to Ottaviano and Peri (2012).\footnote{For full-time wages of men and women combined, with no fixed effects, Ottaviano and Peri estimate a $\beta_1$ of -0.044: see column 4 of their Table 2. The small difference is partly due to our extended year sample (we include 2010 and 2017) and restricted wage sample (like Borjas, 2003, we exclude students).} Under the hypothesis of equal mark-downs $H1$ (i.e. $\Delta \phi_0 = \Delta \phi_1 = 0$), $\beta_0$ identifies within-cell productivity differentials $\log \bar{\alpha}_Z$, and $\beta_1$ identifies $-(1 - \sigma_Z)$, implying an elasticity of substitution of $\frac{1}{1-\sigma_Z} = 30$ between natives and migrants. But in general, these parameters cannot be separately identified from differentials in the mark-downs. A negative $\beta_0$ may reflect larger migrant mark-downs ($\Delta \phi_0 > 0$), and a negative $\beta_1$ a greater sensitivity of migrant mark-downs to immigration ($\Delta \phi_1 > 0$).

Our estimates are somewhat sensitive to specification. Adjusting wages for composition in column 2 reduces the coefficients substantially, and especially $\beta_1$: this reflects Ruist’s (2013) findings on migrant cohort effects. One may also be concerned that the relative migrant supply, $\frac{M_{\text{ext}}}{N_{\text{ext}}}$, is endogenous to within-cell relative demand shocks in the error, $u_{\text{ext}}$. In column 3, we attempt to address this problem by instrumenting $\log \frac{M_{\text{ext}}}{N_{\text{ext}}}$.
with \( \log \frac{\tilde{M}_{ext}}{\tilde{N}_{ext}} \), where \( \tilde{M}_{ext} = \tilde{M}_{new}^{ext} + \tilde{M}_{old}^{ext} \) is the total predicted migrant employment (described above), and \( \tilde{N}_{ext} \) is predicted native employment. The first stage has considerable power: see Panel B. But, our \( \beta_1 \) estimate in Panel A remains at zero. Following Ottaviano and Peri, we next respecify \( \alpha_{Zext} \) to include interacted education-experience and year fixed effects:

\[
\alpha_{Zext} = \alpha_{Zex} + \alpha_{Zt} + u_{ext}
\]

which now enter our empirical specification. In columns 4-5, instead of a constant, we report the mean intercept across all cells (averaging the fixed effects). \( \beta_1 \) now turns negative again (reaching -0.039 in IV), and the mean \( \beta_0 \) expands. Columns 6-7 estimate the same specifications in first differences: i.e. regressing \( \Delta \log \frac{\tilde{W}_{ext}}{\tilde{W}_{Next}} \) on \( \Delta \log \frac{\tilde{M}_{ext}}{\tilde{N}_{ext}} \) and year effects (the education-experience effects are eliminated). The instrument is also differenced, and it continues to offer substantial power (see column 7 of Panel B). The IV estimate of \( \beta_1 \) remains negative, though a little smaller than under fixed effects. To summarize, our mean \( \beta_0 \) varies from -0.07 to -0.18, and \( \beta_1 \) from zero to -0.039.\(^{20}\)

6.2 Testing the null of equal and independent mark-downs

We now test the null hypothesis of equal and independent mark-downs (i.e. the combination of \( H1 \) and \( H2 \)), of which perfect competition is a special case. To this end, we turn to the equation for native wages (28). We parameterize the cell-level productivity shifter \( A_{ext} \) in (18) as:

\[
A_{ext} = d_{ex} + d_{et} + d_{xt} + v_{ext}
\]

where the \( d_{ex} \) are education-experience interacted fixed effects, the \( d_{et} \) are education-year effects, and the \( d_{xt} \) experience-year effects. Comparing to (18), notice the \( d_{et} \) pick up productivity shocks \( \alpha_{et} \) and labor supply effects at the education nest level; and the \( d_{ex} \) and \( d_{xt} \) account for components of the education-specific experience effects \( \alpha_{ext} \). Any remaining variation in the \( \alpha_{ext} \) (at the triple interaction) falls into the idiosyncratic \( v_{ext} \) term. Our native wage equation (28) can then be estimated using:

\[
\begin{align*}
\log W_{Next} + (1 - \sigma_Z) \log N_{ext} & = \gamma_0 + \gamma_1 \left[ \log (N_{ext}^{\sigma_Z} + \alpha_{Zext} M_{ext}^{\sigma_Z}) \right] \\
& + \gamma_2 \log \frac{M_{ext}}{N_{ext}} + d_{ex} + d_{et} + d_{xt} + v_{ext}
\end{align*}
\]

Based on (28), \( \gamma_1 \) will identify \((\sigma_X - \sigma_Z)\), where \( \sigma_X \) measures the substitutability between experience groups and \( \sigma_Z \) between natives and migrants (within education-experience cells). In turn, \( \gamma_2 \) will identify \( \phi_{1N} \), the impact of migrant composition on native wage

\(^{20}\)Borjas, Grogger and Hanson (2012) find the \( \beta_1 \) coefficient is also sensitive to the choice of regression weights: they recommend using the inverse sampling variance, rather than Ottaviano and Peri’s total employment. In light of this controversy, we have chosen instead to focus on unweighted estimates.
mark-downs. In some specifications, we replace the relative supply variable \( \frac{M_{ext}}{N_{ext}} \) with the migrant share \( \frac{M_{ext}}{N_{ext} + M_{ext}} \): as we argue above, the latter should better represent the mark-down effects. We also estimate first differenced versions of (33), where all variables of interest are differenced and the \( d_{ext} \) fixed effects eliminated.

As we have explained above, under equal mark-downs (\( H1 \)), equation (30) identifies the technology parameters (\( \alpha_Z, \sigma_Z \)). We rely on the \( \beta_0 \) and \( \beta_1 \) estimates in column 5 of Table 2, which imply \( \sigma_Z = 1 - 0.039 \) and a mean log \( \alpha_{Zext} \) of -0.177. These allow us to construct the two bracketed terms (the augmented wage variable and cell aggregator) and estimate (33) linearly. Under the joint null of equal and independent mark-downs (\( H1 \) and \( H2 \)), it must then be that \( \gamma_2 = 0 \); and this can be tested.

The two right hand side variables in (33) rely on different sources of variation: native employment \( N_{ext} \) increases the aggregator log \( (N_{ext}^\sigma_Z + \alpha_{Zext} M_{ext}^\sigma_Z)^{\frac{1}{\sigma_Z}} \) but diminishes the migrant composition log \( \frac{M_{ext}}{N_{ext}} \); whereas migrant employment \( M_{ext} \) increases both. However, there are a number of concerns about their exogeneity. First, omitted demand shocks at the interaction of education, experience and time (in \( v_{ext} \) in (32)) may generate unwanted selection: both through the arrival of new immigrants (see Llull, 2018, Monras, forthcoming) and the human capital choices of existing US residents (Hunt, 2017; Llull, 2017). Second, native employment \( N_{ext} \) appears on both the left and right hand sides; so any measurement error in \( N_{ext} \) or misspecification of the technology will mechanically threaten identification. Beyond this, measurement error will be a problem for the cell aggregator log \( (N_{ext}^\sigma_Z + \alpha_{Zext} M_{ext}^\sigma_Z)^{\frac{1}{\sigma_Z}} \), which is a generated regressor and therefore contains noise. To address these challenges, we construct instruments for the two right hand side variables by combining our predicted native and migrant stocks, \( \tilde{N}_{ext} \) and \( \tilde{M}_{ext} \): we instrument log \( \frac{M_{ext}}{N_{ext}} \) using log \( \frac{M_{ext}}{\tilde{N}_{ext}} \), and log \( (N_{ext}^\sigma_Z + \alpha_{Zext} M_{ext}^\sigma_Z)^{\frac{1}{\sigma_Z}} \) using log \( (\tilde{N}_{ext}^\sigma_Z + \alpha_{Zext} \tilde{M}_{ext}^\sigma_Z)^{\frac{1}{\sigma_Z}} \).

In Panel A of Table 3, we present our first stage estimates for equation (33), imposing the hypothesis of equal mark-downs (\( H1 \)). Each instrument drives its corresponding endogenous variable with considerable power: the Sanderson and Windmeijer (2016) F-statistics, which account for multiple endogenous variables, range from 16 to 83.

Panel A of Table 4 presents the second stage results (we return to Panel B below). Our estimates of \( \gamma_1 \) are mostly positive (which would imply \( \sigma_X > \sigma_Z \)) but close to zero. If \( \sigma_Z \) is close to 1 (as Table 2 suggests, at least under \( H1 \)), these \( \gamma_1 \) estimates would imply \( \sigma_X \approx 1 \), i.e. experience groups are (approximately) perfect substitutes within education nests. This appears to contradict the prevailing view in the literature; but as we show below, our estimates closely match those of Card and Lemieux (2001), the seminal work on this subject, when we use broader education groups.
The effect of migrant cell composition, $\gamma_2$, is universally negative. The statistical significance of $\gamma_2$ leads us to reject the null hypothesis of independent native mark-downs ($H2$), conditional on $H1$. Adjusting native wages for compositional changes (columns 3-4) approximately doubles our $\gamma_2$ coefficient. When we control for the relative supply $\log \frac{M_{ext}}{N_{ext}}$ and migrant share $\frac{M_{ext}}{N_{ext} + M_{ext}}$ simultaneously (in column 5), the latter picks up the entire effect: this suggests $\frac{M_{ext}}{N_{ext} + M_{ext}}$ is the more appropriate functional form for the mark-down effect, which is consistent with our monopsony story. Using IV instead of OLS makes little difference, which suggests selection is not a significant problem in this context.\(^{21}\)

For illustration, identifying cell composition with the migrant share, our IV estimate of $\gamma_2$ is -0.61 (column 7 of Panel A). That is, conditional on $H1$, a 1 pp expansion of the migrant share increases the native mark-down by 0.61%. The first differenced estimates are similar: the equivalent specification yields a $\gamma_2$ of -0.54 (in column 9).

To summarize, the fact that $\gamma_2$ is significantly different from zero allows us to reject the null hypothesis of equal and independent mark-downs (i.e. the joint hypothesis of $H1$ and $H2$). In our model in Section 3, this joint hypothesis corresponds to the case of equal native and migrant elasticities ($\epsilon_N = \epsilon_M$). Crucially, perfect competition (i.e. zero mark-downs) is a special case of this joint hypothesis.

### 6.3 Set identification of key parameters

Above, we have offered a simple two-step procedure which tests (and rejects) the joint hypothesis of equal and independent mark-downs. If we are willing to accept $H1$ (equal mark-downs), our $\gamma_2$ estimates imply a $\phi_{1N}$ of 0.5-0.6. That is, a 1pp increase in the migrant share raises the native mark-down by 0.5-0.6%. However, we are unable to test $H1$ in isolation. If it is not satisfied in reality, the true $\phi_{1N}$ may be entirely different from (the negative of) our $\gamma_2$ estimate: conceivably, even its sign may be incorrect.

Though the full model is not identified, it does imply restrictions on sets of parameters; and this allows us to explore the robustness of our conclusions. For any given $\alpha_Z$ and $\sigma_Z$, we can use the native wage equation (28) to point identify the mark-down effect, $\phi_{1N}$. (And for given $\alpha_Z$ and $\sigma_Z$, we can also identify $\Delta \phi_0$ and $\Delta \phi_1$ using our estimates of the relative wage equation.) Our strategy is therefore to study how $\phi_{1N}$ varies across a broad range of $\alpha_Z$ and $\sigma_Z$ values. This approach offers a form of set identification, in the sense that only some combinations of parameters are consistent with the data.

We begin by considering a specification where, in line with e.g. Borjas (2003), natives and migrants contribute identically to output within education-experience cells: i.e. $\alpha_Z = \sigma_Z = 1$. In this environment, we would attribute any deviation of $\beta_0$ and $\beta_1$ from zero (in the relative wage equation) to the differential competition effects, $\Delta \phi_0$ and $\Delta \phi_1$. Moving

---

\(^{21}\)In contrast, Llull’s (2018) IV estimate of the migrant share effect is more than twice his OLS estimate - though as we have explained above, he uses a different instrument.
to the native wage equation (33), the left hand side collapses to the log native wage log \( W_{Next} \), and the cell aggregator collapses to total employment log \( (N_{ext} + M_{ext}) \). We offer first and second stage estimates for this specification in Panel B of Tables 3 and 4. Unsurprisingly perhaps, the results are similar to Panel A: the \( \alpha_Z \) and \( \sigma_Z \) values implied by \( H1 \) are themselves close to 1. In the fixed effect IV specification (column 7), the coefficient on \( \gamma_1 \) now drops to zero (from 0.04 in Panel A), and the coefficient \( \gamma_2 \) on the migrant share (which identifies \( \phi_{1N} \)) drops to -0.55 from -0.61.

In Figure 2, we now study how our estimate of \( \phi_{1N} \), the effect of migrant share on the native mark-down, varies across a broader range of \( (\alpha_Z, \sigma_Z) \) calibrations.\(^{22}\) In panel A, we focus on the IV fixed effect specification (comparable with column 7 of Table 4), with native wages adjusted for composition.

Compared with other \( (\alpha_Z, \sigma_Z) \) values, our \( \phi_{1N} \) estimates in Table 4 (which hover around 0.5) represent a lower bound. As \( \sigma_Z \) decreases from 1, \( \phi_{1N} \) becomes larger. Intuitively, for a lower \( \sigma_Z \), we are treating natives and migrants as relatively more complementary in technology. This would imply that immigration is relatively more beneficial for native marginal products; and consequently, to account for the observable wage variation, we require a more adverse mark-down effect. Notice the effect of \( \sigma_Z \) diminishes as \( \alpha_Z \) declines: if migrants contribute little to output, they will have less influence on native marginal products, so the value of \( \sigma_Z \) becomes moot. In the limit, when \( \alpha_Z \) reaches zero, the cell aggregator collapses to the native stock; so \( \sigma_Z \) has no influence.

In Panel B of Figure 2, we repeat the exercise for the IV fixed effect specification (comparable to column 9 of Table 4). The effects are much the same, though the (shaded) 95% confidence intervals are wider. We offer more complete regression tables for a selection of \( (\alpha_Z, \sigma_Z) \) values in Appendix Table A1.

### 6.4 Interpretation of results

To summarize, our estimates reject the null hypothesis of equal and independent mark-downs, of which perfect competition is a special case. We are unable to point identify the mark-down response to the migrant share, \( \phi_{1N} \). But comparing a broad range of calibrations, our estimates suggest a 1 pp increase in migrant share increases the native mark-down by at least 0.5% (with larger effects for certain specifications of technology).

What are the implications for native wages overall? We must consider both the marginal products and the mark-downs. As we show above, in the “long run” (with elastic capital), natives’ marginal products must increase on average. Ottaviano and

\(^{22}\)Note that, unlike in Panel A of Table 2, our approach here is to impose equal \( \alpha_Z \) values in every labor market cell.
Peri (2012), for example, predict that migration caused native wages to grow by 0.6% over 1990-2006, based on simulations of various nested CES structures (calibrated by estimated elasticities of substitution). In some specifications, all native education groups gain; in others, high school dropouts suffer wage declines of up to 2 percent.

How do the mark-down effects compare? Over these same years, the migrant share grew by 7 pp. For a $\phi_{1N}$ of 0.5-0.6, this would imply that mean native wages contracted 4% due to mark-downs (which exceeds the positive effect from marginal products). Among high school dropouts, who saw a 24 pp increase in migrant share over the period, the implied mark-down effect is about three times larger.

Until now, we have focused on natives; but our results also speak to the mark-downs of migrants. Again, identification presents a challenge. The coefficient $\beta_1$ in the relative wage equation identifies $-\left(1 - \sigma + \Delta \phi_1\right)$, where $\sigma$ is the native-migrant substitutability, and $\Delta \phi_1$ is the differential response of migrant relative to native mark-downs. Under $H1$, $\Delta \phi_1$ will equal zero by construction; so the mark-down responses will be identical. If instead we assume $\sigma = 1$, our preferred $\beta_1$ estimate of -0.039 would imply $\Delta \phi_1 = 0.039$. So, doubling the relative supply of migrants would cause migrants’ mark-downs to expand by 4% more than natives. In Appendix G.2 and Appendix Figure A1, we study how the migrant mark-down response varies across a broader range of $\alpha_Z$ and $\sigma_Z$ values.

### 6.5 Comparison with existing empirical literature

Of course, we are not the first to estimate a native wage equation across education-experience cells. But equation (33) is distinctive in controlling simultaneously for cell size (i.e. the Armington aggregator) and cell composition (migrant share). Intuitively, the aggregator controls for the impact of immigration on marginal products, allowing the migrant share to identify the mark-down effect.

Borjas (2003; 2014) and Ottaviano and Peri (2012) study a specification with the cell aggregator alone, to estimate the substitutability $\sigma_X$ between experience groups within education nests (building on the earlier work of Card and Lemieux, 2001). Borjas (2003) estimates a coefficient $\gamma_1$ of -0.29 on the cell aggregator (implying an elasticity of substitution of 3.4, assuming $\sigma_Z = 1$), and Ottaviano and Peri’s preferred estimate is -0.16; while our estimates of $\gamma_1$ are zero or slightly positive. However, both Borjas and Ottaviano and Peri instrument the cell aggregator $Z(N, M)$ using total migrant labor hours. This instrument will violate the exclusion restriction if, as our model suggests, migrant composition enters wages independently. In contrast, we identify the effects of the cell aggregator and cell composition separately, using two distinct instruments.

Borjas (2003) also estimates a version of equation (33) which excludes the cell aggregator $Z(N, M)$, implicitly imposing $\gamma_1 = 0$. His motivation is to generate descriptive estimates (i.e. without imposing theoretical structure) of the effect of immigration, using
skill-cell variation. The effect of migrant share varies from -0.5 or -0.6, very similar to our own estimates of $\gamma_2$. His empirical specification has latterly been criticized by Peri and Sparber (2011) and Card and Peri (2016). They note that the native stock in the education-experience cell appears in the denominator of the migrant share $\frac{M_{\text{ext}}}{N_{\text{ext}}+M_{\text{ext}}}$. Unobserved cell-specific demand shocks (which raise wages and draw in natives) may then generate a spurious negative relationship between wages and the migrant share. However, our IV strategy should in principle address this concern.

In short, our estimates are driven by similar variation to previous studies (abstracting from our instruments and residualized wages); but our contribution is to give these effects a different interpretation.

7 Robustness and empirical extensions

7.1 Outliers, wage definition, weighting and instruments

We now consider the robustness of our native wage equation (33) to outliers, wage definition, choice of weighting, and specification of instruments. First, one may be concerned that the migrant share effects, $\gamma_2$, are driven by outliers. To address this, Figure 3 graphically illustrates our OLS and IV estimates of $\gamma_2$, both for fixed effects and first differences, based on columns 4, 7, 8 and 9 of Panel B in Table 4. For simplicity, we impose \( \alpha_Z = \sigma_Z = 1 \), so the dependent variable collapses to log native wages and the cell aggregator to log total employment, \( \log (N_{\text{ext}} + M_{\text{ext}}) \).

For the OLS plot, we partial out the effect of the controls (i.e. log total employment and the various fixed effects) from both native wages (on the y-axis) and migrant share (on the x-axis). For IV, we first replace both (i) log total employment and (ii) migrant share with their linear projections on the instruments and fixed effects; and we then follow the same procedure as for OLS. By construction, the slope coefficients are identical to the $\gamma_2$ estimates in Panel B of Table 4. And by inspection of the plots, it is clear these effects are not driven by outliers. On the contrary, the correlation between the partialled variables is remarkably strong, at least in the fixed effect specifications.

In Appendix Table A2, we show our IV estimates of $\gamma_2$ are robust to the choice of wage variable and weighting. We study the wages of native men and women separately, and hourly wages instead of full-time weekly wages; and we experiment with weighting observations by total cell employment. But the effect of the migrant share is little affected.

One may also be concerned that our predictor for the migrant stock, $\tilde{M}_{\text{ext}}$, is largely noise; and that the first stage is driven instead by the correlation between native employment $N_{\text{ext}}$ and its predictor $\tilde{N}_{\text{ext}}$ (which appear in the denominators of the migrant
share $\frac{M_{ext}}{N_{ext} + M_{ext}}$ and its instrument $\frac{\tilde{M}_{ext}}{\tilde{N}_{ext} + \tilde{M}_{ext}}$). See Clemens and Hunt (2019) for a related criticism. But in Appendix Table A3, we show our IV estimates are robust to replacing the migrant share instrument $\frac{\tilde{M}_{ext}}{\tilde{N}_{ext} + \tilde{M}_{ext}}$ with its numerator $\tilde{M}_{ext}$.

7.2 Broad education and experience groups

We next study an alternative specification with two (instead of four) education groups. As Card (2009) notes, a four-group scheme implicitly constrains the elasticity of substitution between any two groups to be identical; but there is evidence that high-school graduates and dropouts are closer substitutes with each other than with college graduates. For this exercise, we divide workers into “college-equivalents” (which include all college graduates, plus 0.8 times half of the some-college stock) and “high-school equivalents” (high school graduates, plus 0.7 times the dropout stock, plus 1.2 times half of the some-college stock): the weights, borrowed from Card (2009), have an efficiency unit interpretation. This leaves us with just 16 clusters (since we cluster by labor market cell); but at least in this data, the bias to the standard errors appears to be small.\textsuperscript{23}

We report OLS and IV estimates in columns 1-4 of Table 5; and we leave the first stage estimates to Appendix Table A4. For simplicity, we continue to impose $\alpha_Z = \sigma_Z = 1$. Notice that $\gamma_1$ (the elasticity to total cell employment) is now consistently negative and lies around -0.1. For $\sigma_Z = 1$, this implies an elasticity of substitution between experience groups (within education nests) of 10. These estimates are consistent with those of Card and Lemieux (2001), who use an equivalent two-group education classification.\textsuperscript{24}

The $\gamma_2$ estimates (on migrant share) now increase to -1 in the OLS and IV fixed effect specifications. The first differenced estimates remain closer to -0.5; but the standard errors in IV now balloon, which reflects the weakness of the instruments (as Appendix Table A4 shows, the F-statistics are below 4).

In columns 5-8 of Table 5, we also re-estimate our model using four 10-year experience groups (rather than eight 5-year groups), while keeping the original four-group education classification. This appears to make little difference to our baseline estimates in Table 4.

To summarize, conditional on cell size, the effect of migrant share on native wages appears to be reasonably robust to alternative skill group definitions.

\textsuperscript{23}For just 16 clusters, one may fear that asymptotic inference is invalid - even after applying the small-sample corrections recommended by Cameron and Miller (2015), as we do for both OLS and IV. However, the bias in this data appears to be small. For example, consider the OLS coefficient on $\frac{M_{ext}}{N_{ext} + M_{ext}}$ in column 1 of Table 5. Since we have 16 clusters, we apply the 95% critical value of the $T(15)$ distribution, which is 2.13. The standard error in column 1 then implies a confidence interval of $[-1.324, -0.783]$. But the wild bootstrap recommended by Cameron, Gelbach and Miller (2008), which we implement with Roodman et al.’s (2019) “boottest” command, delivers a very similar interval of $[-1.310, -0.775]$.

\textsuperscript{24}In their main specification, they estimate an elasticity of substitution of 5 across age (rather than experience) groups; but they also offer estimates across experience groups which are similar to ours.
7.3 Heterogeneous effects by education and experience

Another pertinent question is whether the mark-down effects differ across labor market cells. To study this heterogeneity, we alternately interact the migrant share in (33) with a college dummy (taking 1 for cells with any college education) and a high-experience dummy (for 20+ years). These interactions require additional instruments: we use the interactions between the predicted migrant share and the college/experience dummies.

We report our first stage estimates in Appendix Tables A5 and A6, and the OLS and IV estimates in Table 6. In OLS, the migrant share responses (which identify the mark-down effects) are entirely driven by non-college workers, both in the fixed effect and first differenced specifications. Intuitively, one might expect that lower income migrants suffer disproportionately from a lack of outside options, allowing employers to extract relatively more rents from their native co-workers. Still, we do not find differential effects by education in IV, though the first stage F-statistics are small (never above 5). With respect to experience, we find no evidence of heterogeneous effects in OLS or IV.

7.4 Heterogeneous effects of new and old migrants

We next explore whether mark-downs are more responsive to newer migrants. On the one hand, newer migrants may supply labor less elastically to firms, allowing them to extract larger rents from labor. However, they may also be less assimilated into native labor markets, so there may be less direct competition (see the discussion in Section 3.4).

Our approach is to control separately for the shares of new migrants $\frac{M_{N_{ext}}^{new}}{N_{ext} + M_{ext}}$ (in the US for up to new years) and old migrants $\frac{M_{N_{ext}}^{old}}{N_{ext} + M_{ext}}$ (more than ten years) in the native wage equation (33). We construct distinct instruments for each, i.e. $\frac{\tilde{M}_{N_{ext}}^{new}}{N_{ext} + M_{ext}}$ and $\frac{\tilde{M}_{N_{ext}}^{old}}{N_{ext} + M_{ext}}$. Appendix Table A7 reports the first stage: our instruments perform remarkably well in fixed effects, but $\frac{\tilde{M}_{N_{ext}}^{new}}{N_{ext} + M_{ext}}$ has no explanatory power in first differences.

Table 7 presents our OLS and IV estimates. In the fixed effect specification (columns 3-4), there is no significant difference in the impact of new and old migrants. In first differences though, the standard errors are generally too large to identify their effect.

7.5 Impact on employment rates

We focus in this paper on wage effects, and we have taken employment as given throughout. But, Dustmann, Schoenberg and Stuhler (2016) have stressed the importance of
labor supply responses to migration; and Borjas (2003) and Monras (forthcoming) have estimated effects on native employment rates as well as wages, exploiting similar skill-cell variation to us. This question is especially pertinent in the context of monopsony: Chassamboulli and Palivos (2013) and Chassamboulli and Peri (2015) argue that migrants’ low wage demands may stimulate job creation; and Albert (2017) and Amior (2017) note that, under certain parameterizations, such a job creation effect may dominate any adverse wage effects in the determination of native welfare. However, if the job creation response is weak, native employment may also contract - in response to the lower wages.

To estimate the elasticity of employment to wages, we use the following specification:

$$\log ER_{next} = \delta_0 + \delta_1 \log W_{next} + d_{ex} + d_{et} + d_{xt} + e_{ext}$$

where \(\log ER_{next}\) is the log of mean annual native employment hours. Like Borjas (2003), we exclude enrolled students from our employment rate sample. The regressor of interest is the (composition-adjusted) log native wage, and we control for the full set of interacted fixed effects. We also study first differenced specifications, where the \(d_{ex}\) effects are eliminated. Borjas (2017) uses a similar specification to estimate employment elasticities; we build on his work by adjusting employment rates for changes in demographic composition (as we do for wages\(^{25}\)) and by instrumenting wages using migration shocks.

We present estimates of the native employment elasticity \(\delta_1\) in Panel A of Table 8. For raw employment rates, our OLS estimate is 0.5 using fixed effects (column 1) and 0.9 in first differences (column 5). After adjusting employment for composition, these become 0.7 (column 2) and 0.8 (column 6) respectively.

Of course, the OLS estimates may be conflated with omitted cell-specific demand shocks. In columns 3 and 7, we now introduce the instruments from our native wage equation: (i) predicted log total employment (in the labor market cell) and (ii) predicted migrant share. It is worth stressing that our instruments are constructed using population (and not employment) data, so they are not conflated with variation in employment rates. The first stage in Panel C can be interpreted as a reduced form wage equation, regressing wages directly on the instruments. Consistent with our findings in Table 4, only the predicted migrant share has power; and we also offer an “IV2” specification which excludes the total employment instrument.

Turning to the second stage, IV yields much larger native employment elasticities, reaching 1.2 for fixed effects (column 4) and 1.3 for first differences (column 8). Notice

\(^{25}\)Our motivation for adjusting employment rates is the same as for wages: changes in either outcome may be conflated with observable demographic shifts (within education-experience cells). We follow identical steps to those described in Section 4.2; but this time, we estimate linear regressions for annual employment hours (including zeroes for individuals who do not work) rather than log wages.
these estimates are identified entirely from the predicted migrant share, which our model associates with the mark-down channel. This suggests that larger mark-downs, driven by immigration, have eroded native employment rates.

In Panel B, we repeat the exercise for migrants, replacing the employment rate and wage variables with migrant equivalents. Our $\delta_1$ estimates are universally smaller than those of natives. The IV estimates are difficult to interpret because of weak instruments (see the first stage in Panel D), but we do see similar patterns in OLS. This suggests that migrants supply labor relatively inelastically to the market, which reflects the evidence from Borjas (2017). Of course, this is not the same as migrants supplying labor inelastically to individual firms (i.e. $\epsilon_M < \epsilon_N$). But the two stories are certainly consistent, and this offers additional support for our interpretation of the mark-down effects: firms are able to set larger mark-downs by exploiting an inelastic supply of migrant labor.

8 Conclusion

Under the assumption of constant returns, we show that a larger supply of migrants (keeping their skill mix constant) must always increase the marginal products of native-owned factors on average, unless natives and migrants have identical skill mixes. And in the long run (if capital is supplied elastically), this surplus passes entirely to native labor. This extends Borjas’ (1995) “immigration surplus” results to a wide class of models with many types of labor and goods. But in a monopsonistic labor market, wages will also depend on any mark-downs imposed by firms. If migrants supply labor to firms less elastically than natives (and there is evidence to support this claim), firms can exploit immigration by imposing larger mark-downs (relative to marginal products) on the wages of natives and migrants alike.

We develop a test of the hypothesis that native and migrant mark-downs are equal and independent of the migrant share, of which perfect competition (and zero mark-downs) is a special case; and we reject this hypothesis using standard US data on employment and wages. Under an alternative framework with monopsonistic firms, our estimates suggest that immigration may in fact depress mean native wages overall - even in a “long-run” setting with perfectly elastic capital.

It is worth stressing that the policy implications are nuanced: one cannot conclude that migration is generally harmful for native workers. If policy interventions can make the labor market more competitive (by limiting the power of firms to set mark-downs), immigration would only have the surplus-raising feature. See e.g. Edo and Rapoport (2017) for evidence on minimum wages. On the other hand, as we have noted in the introduction, interventions ostensibly designed to protect native wages by stemming the flow of migrants (such as restricting access of migrants to welfare benefits) may be self-defeating, if they make the labor market less competitive. Whether the impact of immigration is
affected by labor market institutions may be a fruitful topic for further investigation.

34

Ottaviano, Gianmarco I.P., and Giovanni Peri. 2012. “Rethinking the Effect of

A The long-run production function

Suppose the production function can be written as $F(L, K)$, where $L$ is a vector of inputs that are treated as fixed (perhaps because they are in inelastic supply or simply for analytical convenience) and $K$ a vector of other inputs (possibly including capital) that are in perfectly elastic supply at prices $p_K$. Assume the production function has constant returns to scale in all its inputs. For given $L$, let $\Pi$ represent the profits net of the cost of non-labor inputs:

$$\Pi(L, p_K) = \max_K \{ F(L, K) - p'_K K \}$$  \hfill (A1)

The purpose of this appendix is to show that $\Pi$ can be treated as a “long run” production function with constant returns in the $L$ inputs, and whose derivatives equal their marginal
products.

Notice first that the first-order conditions for profit maximization can be written as:

\[ F_K(L, K) = p_K \]  \hspace{1cm} (A2)

These first-order conditions can be solved to write the optimal choice of inputs as a function \( K(L, p_K) \) of \( L \) and input prices. From the assumption of constant returns, \( K(L, p_K) \) must be \textit{Hod1} in \( L \). Substituting this for \( K \) in (A1) gives:

\[ \Pi(L, p_K) = F(L, K(L, p_K)) - p_K K'(L, p_K) \]  \hspace{1cm} (A3)

which is a function of \( L \) and \( p_K \) alone. Since \( K(L, p_K) \) is \textit{Hod1} in \( L \), the net profit function \( \Pi(L, p_K) \) must have constant returns in \( L \). Also, the derivatives of the net profit function must equal the marginal products of the respective labor inputs. To see this, notice that:

\[ \Pi_L(L, p_K) = F_N(L, K(L, p_K)) + [F_K - p_K] \frac{\partial K(L, p_K)}{\partial L} = F_L(L, K(L, p_K)) \]  \hspace{1cm} (A4)

where the second equality follows from (A2).

Therefore, assuming non-labor inputs are elastically supplied, we can write the long-run production function as \( \tilde{F}(L) = \Pi(L, p_K) \) in the main body of the paper, where we suppress the dependence on \( p_K \) for notational convenience.

\[ \text{B Proof of Proposition 4} \]

Proposition 4 follows from Proposition 3 with the following modification. Instead of defining natives and migrants as the two distinct groups, define the two groups as those with skill mix vector \( \eta \) and those with skill mix \( \mu \). Let \( \tilde{N} \) be the first group’s vector of employment stocks (across skill types), and \( \tilde{M} \) the second group’s vector. Based on (6), the \( \tilde{N} \) group consists of all natives and a fraction \( 1 - \zeta \) of migrants:

\[ \tilde{N} = N + (1 - \zeta) M \]  \hspace{1cm} (A5)

and the \( \tilde{M} \) group consists of the remaining migrants:

\[ \tilde{M} = \zeta M \]  \hspace{1cm} (A6)

An increase in \( \zeta \) diminishes the first group but expands the second. From Proposition 3, we know this must increase the average wage of the first group. This group is not exclusively composed of natives. But the natives and migrants in this group have, by
construction, the same skill mix; so the average wage must be the same for both these components of the group. Hence, the average wage of natives must rise. Note that the average wage of migrants may also rise, because a change in the skill mix may shift the group composition towards skills that yield higher wages in equilibrium.

C Proof of Proposition 5

C.1 Production

Suppose there are $K$ industries in a closed economy, all of which produce goods with the $J$ different types of labor (and possibly the $K$ goods as intermediate inputs) using a constant returns to scale production function. If the goods market is competitive, the price of each good will equal its unit cost function:

$$p = \tilde{c}(w, p)$$  
(A7)

where $p$ is the $K \times 1$ vector of prices, and the cost function $\tilde{c}$ will depend on the $J \times 1$ vector of wages $w$ and (if there are intermediate or capital good inputs) the vector of goods prices.\(^{26}\) From standard theory, $\tilde{c}$ will be homogenous of degree 1 in its arguments, increasing and concave. One can solve (A7) to give a “reduced form” cost function:

$$p = c(w)$$  
(A8)

This cost function $c$ must also be homogeneous of degree 1 in its arguments.

Let $a_{kj}(w)$ denote the quantity of factor $j$ demanded for producing one unit of good $k$ (both directly and indirectly through the intermediate inputs), and let $A(w)$ denote the $K \times J$ matrix of these factor demands. By Shephard’s lemma, the vector $A(w)$ can be obtained by differentiating the cost function $c$ with respect to wages:

$$c_w(w) = A(w)$$  
(A9)

C.2 Consumption

Now consider the consumer side. To keep things simple, we assume every consumer, native and migrant, has the same homothetic utility function; so the expenditure function can be written as $\tilde{e}(p) u$, where $p$ is the price vector and the level of utility is $u$. It will be convenient to write this expenditure function not (as is usual) in terms of prices, but

\(^{26}\) As Caselli and Manning (2019) note, the rental price of capital should equal the user cost - which is $(r + \delta)$ times the purchase price of the relevant intermediate good, where $r$ and $\delta$ are the rates of interest and depreciation respectively.
rather in terms of wages - using (A8). Per utility expenditure can be written as:

\[ e(w) = \tilde{e}(c(w)) \]  

(A10)

where \( e(w) \) will be an increasing, concave function of its arguments and homogeneous of degree 1. That is, it will behave identically to a normal expenditure function. It is useful to imagine consumers as demanding different types of labor (which produce the goods they consume), rather than demanding the goods directly. These derived demands for labor can be written as:

\[ L(w, u) = e_w(w) u \]  

(A11)

To see how, notice that differentiating (A10) with respect to wages yields:

\[ e_w(w) = \tilde{e}_p(c(w)) c_w(w) = X(c(w)) A(w) \]  

(A12)

where \( X(p) \) is the per utility demands for goods. And consequently, the product of \( X \) and \( A \) is equal to the factor demands for unit utility - from which (A11) follows.

### C.3 Introducing natives and migrants

Suppose there are \( N \) natives and \( M \) migrants in total. Natives and migrants differ in their per capita factor supplies: denote the skill mix of natives by \( \eta \) and migrants by \( \mu \). The vector of total labor supply can then be written as:

\[ L = N\eta + M\mu \]  

(A13)

Since natives and migrants differ in skill mix, they may have different levels of utility in equilibrium. Let \( u^n \) denote the average utility of natives, and \( u^m \) the average utility of migrants.\(^{27}\) As total income must equal total expenditure for natives and migrants alike, we must have:

\[ \eta w = e(w) u^n \]  

(A14)

and

\[ \mu w = e(w) u^m \]  

(A15)

Finally, supply must equal demand in each of the labor markets. This equilibrium condition can be written as:

\[ N\eta + M\mu = e_w(w) [Nu^n + Mu^m] \]  

(A16)

\(^{27}\)Because of the homotheticity assumption, we can focus on the average level of utility - and we do not have to worry about the distribution of utility.
where the left-hand side is supplies of labor, and the right-hand side the derived demand of different types of labor from native and migrant consumers, using (A11). (A16) can conveniently be rewritten as:

\[ N [\eta - e_w (w) u^n] + M [\mu - e_w (w) u^m] = 0 \]  

(A17)

The terms in square brackets represent a “balance of payments condition”: the difference between the factors supplied by each group (natives or migrants) and the factors they demand. If factor supplies are identical for natives and migrants, these terms must both be zero. But if natives and migrants differ in skill mix, this will not be the case.

Equations (A14), (A15) and (A17) appear to consist of \( J + 2 \) equations in \( J + 2 \) unknowns \((w, u_n, u_m)\). But as usual, one of the factor demands is redundant and equilibrium wages are only determined up to a common factor - so they must be normalized in some way.

### C.4 Assessing the impact of immigration

We want to know what happens when the number of migrants \( M \) increases, holding constant their skill mix \( \mu \). Differentiating (A14) leads, after some rearrangement, to:

\[ e (w) du^n = [\eta - u^n e_w (w)] dw \]  

(A18)

That is, native utility grows (on average) if wages increase more for the types of labor they supply than the implied labor in the goods they buy. And differentiating (A14) leads to a similar equation for migrant utility (in the host country):

\[ e (w) du^m = [\mu - u e^m_w (w)] dw \]  

(A19)

Multiplying (A18) by \( N \) and (A19) by \( M \), and using (A17), then leads to:

\[ M du^m = -N du^n \]  

(A20)

which implies that average native and migrant utility must move in opposite directions, if there is any change at all. But this does not tell us who gains and who loses.\(^{28}\) This would require an expression for the change in wages. Differentiating (A17) leads to:

\[ dM [\mu - e_w (w) u^m] = dw [e_{ww} (w) [Nu^n + Mu^m] + e_w (w) [Ndu^n + Mdu^m]] \]  

(A21)

\(^{28}\)Note that this is migrant utility in the host country: it says nothing about whether there are gains from migration as a whole.
Using (A20), the final term must equal zero. Multiplying both sides by $dw$ then gives:

$$dM \left[ \mu - e_w (w) u^m \right] dw = \left[ Nu^n + Mu^m \right] d\bar{w} e_{ww} (w) dw \quad (A22)$$

and substituting (A19) into the left-hand side:

$$dMe (w) du^m = \left[ Nu^n + Mu^m \right] d\bar{w} e_{ww} (w) dw \quad (A23)$$

The right-hand side of (A23) is negative, because it contains a quadratic form in which the middle matrix is negative semi-definite (from concavity of the expenditure function). This means that migrant utility (in the host country) must fall, or at least not rise; and from (A20), it then follows that native utility must rise, or at least not fall. The effect will be zero if the factor content of the goods demanded by migrants is identical to the factors which they supply: in this case, we would have $dw = 0$, as can be seen from (A18) or (A19).

### D Aggregation of monopsony model

#### D.1 Aggregation of production

The purpose of this appendix is to describe how our simple monopsony model for a single unobservable submarket $j$, outlined in Section 3.2, can be aggregated to the national level (or to any observable labor market cell). At the aggregate level, suppose there are $M$ migrants, a fraction $\mu_j$ of which are exogenously allocated to submarket $j$; and there are $N$ natives, who are allocated according to fraction $\eta_j$. The economy consists of many such submarkets $j$, whose long run output (net of the costs of elastic inputs) is aggregated according to the function $\bar{F} (L_j, .., L_J)$, which we assume to be homogeneous of degree 1. As we have described in Section 3.2, natives and migrants are perfect substitutes within these submarkets.

Following equation (4) and Proposition 3, we can define an aggregate production function in terms of $N$ and $M$ as:

$$Z (N, M) = \bar{F} \left( (\eta_1 N + \mu_1 M), .., (\eta_J N + \mu_J M) \right) \quad (A24)$$

The partial derivative of $Z$ with respect to $N$ is:

$$Z_N (N, M) = \sum_j \eta_j \bar{F}_j \quad (A25)$$

which is the mean marginal product of natives. Similarly, the partial derivative with
respect to $M$ is:

$$Z_M (N, M) = \sum_j \mu_j \tilde{F}_j$$  \hspace{1cm} (A26)$$

which is the mean marginal product of migrants. In this way, we have reduced $\tilde{F}$ to an aggregated production function over two composite inputs ($N$ and $M$), whose marginal products are equal to those of the average native and migrant. The feasibility of this aggregation follows from a long-standing literature on the aggregation of production functions (Houthakker, 1955; Levhari, 1968; Jones, 2005; Growiec, 2008). This literature offers a range of methods to achieve this where the two inputs are capital and labor, rather than natives and migrants. Levhari (1968) in particular shows how one can construct an underlying $\tilde{F}$ from a desired $Z$, using as an example the case where $Z$ is CES.

### D.2 Average wages

Using (8), the average wage in submarket $j$ is:

$$\log W_j = \log \tilde{F}_j - \log \left(1 + \epsilon_j^{-1}\right)$$  \hspace{1cm} (A27)$$

where $\tilde{F}_j$ is the marginal product of submarket $j$ labor; and the second term is the markdown, which depends on the elasticity $\epsilon_j$ of labor supply to firms in the submarket. In turn, $\epsilon_j$ is a weighted average of native and migrant elasticities ($\epsilon_N$ and $\epsilon_M$); and using (9), it can be written as a function of the migrant and native submarket allocations:

$$\epsilon \left(\frac{\mu_j M}{\eta_j N}\right) = \epsilon_N + \frac{\mu_j M}{\mu_j M + \eta_j N} (\epsilon_M - \epsilon_N)$$  \hspace{1cm} (A28)$$

If natives supply labor more elastically ($\epsilon_N > \epsilon_M$), $\epsilon_j$ will be decreasing in the migrant share.

Let $W_N$ be the mean native wage. This will be a weighted average of the wages (A27) across the various submarkets, with weights equal to $\eta_j$:

$$\log W_N = \log Z_N (N, M) - \phi_N \left(\frac{M}{N}\right)$$  \hspace{1cm} (A29)$$

where we have applied the aggregation in (A25), and where $\phi_N$ is the native aggregate markdown:

$$\phi_N \left(\frac{M}{N}\right) = \log \frac{\sum_j \eta_j \tilde{F}_j \left[1 + \epsilon \left(\frac{\mu_j M}{\eta_j N}\right)^{-1}\right]}{\sum_j \eta_j \tilde{F}_j}$$  \hspace{1cm} (A30)$$

which is a function of the migrant share. Similarly, the mean migrant wage can be written as:

$$\log W_M = \log Z_M (N, M) - \phi_M \left(\frac{M}{N}\right)$$  \hspace{1cm} (A31)$$
where \( \phi_M \) is the migrant aggregate mark-down:

\[
\phi_M \left( \frac{M}{N} \right) = \log \frac{\sum_j \mu_j \tilde{F}_j \left[ 1 + \epsilon \left( \frac{\mu_j M}{\eta_j N} \right)^{-1} \right]}{\sum_j \mu_j \tilde{F}_j}
\]

(D.3) Properties of the aggregate mark-down functions

We now explore the properties of the aggregate mark-down functions \( \phi_N \left( \frac{M}{N} \right) \) and \( \phi_M \left( \frac{M}{N} \right) \). First, consider the special case where the submarkets \( j \) are completely segregated (i.e. each is entirely composed of either natives or migrants, so \( \mu_j \eta_j = 0 \) for all \( j \)), whether due to skills or discrimination. This implies that \( \phi_j = \log \left( 1 + \epsilon_N^{-1} \right) \) in all native markets (where \( \eta_j > 0 \), so the aggregate native mark-down \( \phi_N \left( \frac{M}{N} \right) \) depends only on the native supply elasticity. Similarly, complete segregation implies that \( \phi_j = \log \left( 1 + \epsilon_M^{-1} \right) \) in all migrant submarkets (where \( \mu_j > 0 \), so the migrant mark-down \( \phi_M \left( \frac{M}{N} \right) \) will only depend on the migrant elasticity.

However, if there is any overlap of natives and migrants across submarkets \( j \), the aggregate mark-downs will depend on the migrant share (except under the null hypothesis of interest, where \( \epsilon_N = \epsilon_M \)). To study this dependence, consider first the extreme ends of the support. As \( \frac{M}{N} \to 0 \), both the aggregate native and migrant mark-downs (i.e. \( \phi_N \) and \( \phi_M \)) will converge to \( \log \left( 1 + \epsilon_N^{-1} \right) \), i.e. a function only of the native supply elasticity. Similarly, as \( \frac{M}{N} \to \infty \), both \( \phi_N \) and \( \phi_M \) will converge to \( \log \left( 1 + \epsilon_M^{-1} \right) \), a function only of the migrant elasticity.

More generally, for intermediate values of \( \frac{M}{N} \), the differential between the aggregate migrant and native mark-downs (\( \phi_M \) and \( \phi_N \)) will depend on the submarket elasticity function \( \epsilon \left( \frac{\mu_j M}{\eta_j N} \right) \) and the differential between \( \epsilon_M \) and \( \epsilon_N \). Define \( \tilde{\eta}_j = \frac{\eta_j \tilde{F}_j}{\sum_j \eta_j \tilde{F}_j} \) and \( \tilde{\mu}_j = \frac{\mu_j \tilde{F}_j}{\sum_j \mu_j \tilde{F}_j} \). From (A30) and (A32), we then have that:

\[
\exp(\phi_M) - \exp(\phi_N) = \sum_j \tilde{\mu}_j \left[ 1 + \epsilon \left( \frac{\mu_j M}{\eta_j N} \right)^{-1} \right] - \sum_j \tilde{\eta}_j \left[ 1 + \epsilon \left( \frac{\mu_j M}{\eta_j N} \right)^{-1} \right] \text{ (A33)}
\]

\[
= \sum_j \tilde{\eta}_j \left( \frac{\tilde{\mu}_j}{\tilde{\eta}_j} \right) \left[ 1 + \epsilon \left( \frac{\mu_j M}{\eta_j N} \right)^{-1} \right] - \sum_j \tilde{\eta}_j \left[ 1 + \epsilon \left( \frac{\mu_j M}{\eta_j N} \right)^{-1} \right]
\]

\[
= E_{\eta} \left[ \frac{\tilde{\mu}_j}{\tilde{\eta}_j} \left( 1 + \epsilon \left( \frac{\mu_j M}{\eta_j N} \right)^{-1} \right) \right] - E_{\eta} \left[ \frac{\tilde{\mu}_j}{\tilde{\eta}_j} \right] E_{\eta} \left[ 1 + \epsilon \left( \frac{\mu_j M}{\eta_j N} \right)^{-1} \right]
\]

\[
= Cov_{\eta} \left[ \frac{\tilde{\mu}_j}{\tilde{\eta}_j} , \epsilon \left( \frac{\mu_j M}{\eta_j N} \right)^{-1} \right]
\]

where the expectation \( E_{\eta} \) is taken with respect to the distribution \( \tilde{\eta}_j \), and we are using the fact that \( E_{\eta} \left[ \frac{\tilde{\mu}_j}{\tilde{\eta}_j} \right] = 1 \). If \( \epsilon_N > \epsilon_M \) (i.e. if natives supply labor to firms more elastically
than migrants), the overall submarket elasticity \( \epsilon \left( \frac{\mu_j M_j}{\eta_j N_j} \right) \) will be a decreasing function of the ratio \( \frac{\mu_j}{\eta_j} \); so the covariance in the final line of (A33) will be positive, and the aggregate mark-down will be larger for migrants. Intuitively, migrants will be disproportionately located in migrant-intensive submarkets which are less competitive. But as mentioned above, the differential between \( \phi_M \) and \( \phi_N \) must converge to zero as the overall native-migrant ratio \( \frac{M}{N} \) goes to either zero or \( \infty \). And consequently, the differential will not be monotonic in \( \frac{M}{N} \).

E Functional form of mark-down effects

In this appendix, we study the relationship between the mark-down \( \phi_j \) in submarket \( j \) and the migrant cell composition. We argue that a linear relationship between \( \phi_j \) and the migrant share \( \frac{M_j}{N_j + M_j} \) offers a better approximation than a linear with the relative log migrant supply \( \log \left( \frac{M_j}{N_j} \right) \).

In our model, the mark-down depends on the migrant share if the elasticity of labor supply to firms is different for natives and migrants, i.e. if \( \epsilon_N \neq \epsilon_M \). From (9), the elasticity of labor supply facing firms in a given submarket \( j \) is equal to:

\[
\epsilon_j = \epsilon_N + \frac{M_j}{N_j + M_j} \Delta \epsilon
\]  

(A34)

where \( \frac{M_j}{N_j + M_j} \) is the migrant share in the submarket, \( \epsilon_N \) is the native elasticity, and \( \Delta \epsilon \equiv \epsilon_M - \epsilon_N \) is the difference between the migrant and native elasticities. Note that the overall elasticity \( \epsilon_j \) is linear in \( \frac{M_j}{N_j + M_j} \), with slope equal to the difference in elasticities.

In the wage equations (20) and (21), it is the log of the mark-down \( \phi_j \) which is relevant, rather than the labor supply elasticity \( \epsilon_j \). The mark-down in submarket \( j \) is:

\[
\phi_j = \log \left( 1 + \frac{\epsilon_j}{\epsilon_j} \right)
\]  

(A35)

The derivative of the mark-down with respect to the migrant share is:

\[
\frac{d \phi_j}{d \left( \frac{M_j}{N_j + M_j} \right)} = -\frac{1}{\epsilon_j (1 + \epsilon_j)} \Delta \epsilon
\]  

(A36)

Notice that the migrant share \( \frac{M_j}{N_j + M_j} \) has no effect on the mark-down \( \phi_j \) if the elasticity difference is zero (\( \Delta \epsilon = 0 \)), but a positive effect if migrants supply labor less elastically (\( \Delta \epsilon < 0 \)), and vice versa. And importantly, this is true irrespective of the size of the migrant share.

However, this is not the case for the relationship between \( \phi_j \) and \( \log \left( \frac{M_j}{N_j} \right) \). The
The 1960 census does not report migrants’ year of arrival, but we require this information for the construction of the instruments, as well as for the empirical specifications which disaggregate between new and old migrants (i.e. in Table 7). In particular, we need to know the employment stocks of migrants living in the US for no more than ten years, by country of origin and education-experience cell.

For each country of origin and labor market cell, our strategy is to impute these stocks using the size of the same cohort ten years later. For example, to impute the 1960 stock of new Mexican migrants (with up to ten years in the US) among high school graduates with 25-30 years of labor market experience, we use the 1970 stock of high school graduate Mexicans with 11-20 years in the US and 35-40 years of experience.

We then use the 1970 population stocks to predict the 1960 employment stocks. To this end, we exploit the relationship between these variables in future years, when they are both observed. Specifically, we regress the log employment stock of new migrants, by (i) 164 countries of origin, (ii) 32 education-experience cells and (iii) four census years (1970, 1980, 1990 and 2000), on the log population stock of the same cohort ten years later. To allow for cell-specific deviations, we also control for interacted education-experience-region fixed effects, where we account for 12 regions (North America, Mexico, Other Central America, South America, Western Europe, Eastern Europe and former USSR, Middle East and North Africa, Sub-Saharan Africa, South Asia, Southeast Asia, East Asia, Oceania).

We then use the regression estimates (and fixed effects) to predict the employment stocks of new migrants in 1960, conditional on the within-cohort population stocks in 1970. Our approach here will account for cell differences in employment rates, as well as any systematic contraction of migrant cohorts over time (due to emigration). In particular, the coefficient on the future log population (i.e. ten years later) is 0.88. This
suggests about 10% of immigrants leave the country over each decade, which is consistent with estimates from Ahmed and Robinson (1994).

G Supplementary empirical estimates

G.1 Regression tables corresponding to Figure 2

In Appendix Table A1, we offer complete regression tables (i.e. estimates of the native wage equation (33)) corresponding to a selection of \((\alpha_Z, \sigma_Z)\) values in Figure 2. Notice that column 2 is identical to columns 7 and 9 of Panel B of Table 4.

G.2 Estimates of migrant mark-down effects

In this section, we consider the response of the migrant mark-down to cell composition (i.e. \(\phi_{1N} + \Delta \phi_1\) in (26)), and how this varies across different \(\alpha_Z\) and \(\sigma_Z\) values. We base our analysis on our estimates of the relative wage equation (30) and native wage equation (33). Conditional on \((\alpha_Z, \sigma_Z)\), the \(\gamma_2\) coefficient in the native wage equation identifies (the negative of) the mark-down effect \(\phi_{1N}\); and \(\beta_1\) in the relative wage equation identifies \(-1 - \sigma_Z + \Delta \phi_1\). Therefore, for given \((\alpha_Z, \sigma_Z)\), we can impute the response of the migrant mark-down, \(\phi_{1N} + \Delta \phi_1\).

We focus here on the mark-down response to log relative supply, log \(\frac{M}{N}\), rather than to migrant share, \(\frac{M}{M+N}\). This is because we estimate \(\beta_1\) (in the relative wage equation) as a response to log \(\frac{M}{N}\) (in line with our CES technology); so for consistency, we impute \(\Delta \phi_1\) (for a given \(\sigma_Z\) value) as a response to log \(\frac{M}{N}\) also.

In Appendix Figure A1, we begin by estimating the native mark-down response \(\phi_{1N}\) to log \(\frac{M}{N}\), for a range of \(\alpha_Z\) and \(\sigma_Z\) values, and alternately for the fixed effect and first differenced specifications of the native wage equation (33). This replicates the exercise of Figure 2 (as described in Section 6.3), but we now replace the migrant share \(\frac{M}{M+N}\) with the log relative supply log \(\frac{M}{N}\) in the native wage equation. The numbers are of course different to Figure 2, but the patterns look much the same.

In the bottom two panels of Appendix Figure A1, we now back out the migrant mark-down response, which is equal to \(\phi_{1N} + \Delta \phi_1\). The 95% confidence intervals account for the standard errors in the estimates of both \(\beta_1\) and \(\gamma_2\). For \(\sigma_Z = 1\), the migrant mark-down response varies little with \(\alpha_Z\). The intuition is the same as that described in Section
6.3. Note that $\sigma_Z = 1$ implies the differential mark-down effect is equal to $-\beta_1$ (since $\Delta \phi_1 = \sigma_Z - 1 - \beta_1$), which we estimate as 0.039, based on column 5 of Table 2. Thus, migrants’ mark-downs are increasing somewhat more in migrant share than natives’.

However, for smaller $\sigma_Z$ values, we see a very different picture. While the native mark-downs become much more (positively) responsive to migrant share (as the top two panels of Appendix Figure A1 confirm), the migrant mark-downs respond heavily negatively. Intuitively, since our $\beta_1$ estimate is close to zero, small values of $\sigma_Z$ necessarily generate very negative values of the differential mark-down effect, $\Delta \phi_1$. Given the size of the migrant mark-down response, this may raise questions about the realism of these particular $\sigma_Z$ values.

G.3 Robustness to wage definition and weighting

In Appendix Table A2, we confirm that our IV estimates of the native wage equation (33) are robust to the choice of wage variable and weighting.

In each specification, the right hand side is identical to columns 7 and 9 of Panel B of Table 4, and we also use the same instruments. The only difference is the left hand side variable and the choice of weighting. Odd columns study the wages of native men, and even columns those of native women. Columns 1-2 and 5-6 study weekly wages of full-time workers (as in the main text), and the remaining columns hourly wages of all workers. All wage variables are adjusted for changes in demographic composition, in line with the method described in Section 4.2. The estimates in Panel A are unweighted (as in Table 4); while in Panel B, we weight observations by total cell employment. It turns out the estimates are very similar across all specifications.

G.4 Alternative specification for instrument

One may also be concerned that our predictor for the migrant stock, $\hat{M}_{ext}$, is largely noise; and that the first stage of our native wage equation is driven instead by the correlation between native employment $N_{ext}$ and its predictor $\hat{N}_{ext}$ (which appear in the denominators of the migrant share $\frac{M_{ext}}{N_{ext}+M_{ext}}$ and its instrument $\frac{\hat{M}_{ext}}{N_{ext}+\hat{M}_{ext}}$). See Clemens and Hunt (2019) for a related criticism.

However, in Appendix Table A3, we show the IV estimates are robust to replacing the migrant share instrument $\frac{\hat{M}_{ext}}{N_{ext}+\hat{M}_{ext}}$ with its numerator $\hat{M}_{ext}$. In practice, we scale $\hat{M}_{ext}$ by $10^{-9}$ to make the coefficients visible in the table. For the purposes of this exercise, we impose throughout that $\alpha_Z = \sigma_Z = 1$, so the dependent variable collapses to log native wages and the cell aggregator to log total employment, $\log (N_{ext} + M_{ext})$. Columns 1-4 are
otherwise identical to columns 3-6 in Table 3 (Panel B), and columns 5-6 are comparable to columns 7 and 9 in Table 4 (Panel B).

The instruments take the correct sign in the first stage: in particular, the migrant share is decreasing in \(\log (\tilde{N}_{ext} + \tilde{M}_{ext})\) but increasing in \(\tilde{M}_{ext}\); and the associated F-statistics are reasonably large, especially in first differences. Comparing the second stage estimates to Table 4, the standard errors are unsurprisingly larger. But the coefficients are similar in magnitude: the fixed effect estimate is somewhat smaller (decreasing from -0.55 to -0.41), but the first differenced estimate is larger (increasing from -0.47 to -0.68).

### G.5 Supplementary first stage estimates

In Appendix Table A4, we report first stage estimates corresponding to the IV specifications in Table 5 in the main text. In Appendix Tables A5 and A6, we do the same for the IV specifications in Table 6. And Appendix Table A7 reports first stage estimates corresponding to Table 7.

Panel A reports the migrant employment share in 1960, across the four education and eight experience groups; and Panel B reports changes in this share over 1960-2017. Panel C reports changes over 1960-2017 in composition-adjusted log native (weekly) wages, normalized to mean zero across all groups. Panel D reports the mean composition-adjusted log migrant-native wage differential, averaged over 1960-2017, in education-experience cells. The wage sample consists of full-time workers who are not enrolled as students. Wages are adjusted for cell-level changes in demographic composition, according to the procedure described in Section 4.2.

Panel A reports estimates of equation (30), across 32 education-experience cells and 7 year observations (over 1960-2017). Columns 1-3 include no fixed effects, while columns 4-5 control for interacted education-experience and year fixed effects. The "constant" row in these columns reports the mean intercept (accounting for the fixed effects) across all cells. Finally, columns 6-7 are estimated in first differences, controlling for year effects. Panel B reports first stage coefficients for the IV estimates, where the instrument is the log ratio of the predicted migrant to native employment. Robust standard errors, clustered by 32 education-experience cells, are in parentheses. We adjust these for degrees of freedom, scaling them by $\sqrt{G-1 \cdot N-1/N-K}$ for both OLS and IV, where $G$ is the number of clusters, and $K$ the number of regressors and fixed effects. The relevant 95% critical value for the $T$ distribution (with $G - 1 = 31$ degrees of freedom) is 2.04. *** p<0.01, ** p<0.05, * p<0.1.

This table presents first stage estimates for the native wage equation (33), across 32 education-experience cells and 7 year observations (over 1960-2017). There are two endogenous variables: the cell aggregator $\log Z(N,M) = \log (N\sigma_Z + \alpha_Z M\sigma_Z)\frac{1}{\sigma_Z}$ and the cell composition. We consider two specifications for the cell aggregator: in Panel A, we identify $\alpha_Z$ and $\sigma_Z$ using the $\beta_0$ and $\beta_1$ estimates from column 5 of Table 2, under the hypothesis of equal mark-downs ($H1$: $\Delta \phi_0 = \Delta \phi_1 = 0$); and in Panel B, we impose that $\alpha_Z = \sigma_Z = 1$, so $Z(N,M)$ collapses to total employment, $N + M$. We also consider two specifications for the cell composition: columns 1-2 use the log relative migrant-native ratio $\log \frac{M}{N}$, while columns 3-6 use the migrant share $\frac{M}{N + M}$. For each endogenous variable, the corresponding instrument is constructed using the identical functional form over the predicted native and migrant employment, i.e. $\tilde{N}$ and $\tilde{M}$. Columns 1-4 control for interacted education-year, experience-year and education-experience fixed effects; and columns 5-6 are estimated in first differences, controlling for the interacted education-year and experience-year effects. Sanderson-Windmeijer F-statistics account for multiple endogenous variables. Robust standard errors, clustered by 32 education-experience cells, are in parentheses. We apply the same small-sample corrections as detailed in Table 2. The relevant 95% critical value for the $T$ distribution (with $G - 1 = 31$ degrees of freedom, where $G$ is the number of clusters) is 2.04. *** p<0.01, ** p<0.05, * p<0.1.

Panels A and B present OLS and IV estimates of the native wage equation (33), across 32 education-experience cells and 7 year observations (over 1960-2017). The dependent variable is $\log W_N + (1 - \sigma_Z) \log N$, where we use either raw mean or composition-adjusted wages. The two regressors of interest are the cell aggregator $\log Z(N, M) = \log (N \sigma_Z + \alpha_Z M \sigma_Z / \sigma_Z^2 + \alpha_Z \sigma_Z)$ and cell composition. In Panel A, we identify $\alpha_Z$ and $\sigma_Z$ using the $\beta_0$ and $\beta_1$ estimates from column 5 of Table 2, under the hypothesis of equal mark-downs ($H_1$: $\Delta \phi_0 = \Delta \phi_1 = 0$); and in Panel B, we impose that $\alpha_Z = \sigma_Z = 1$, so the dependent variable collapses to the log native wage, and $Z(N, M)$ collapses to total employment, $N + M$. We also consider two specifications for the cell composition: the log relative migrant-native ratio $\log M$ and the migrant share $\frac{M}{N+M}$. Columns 1-7 control for interacted education-year, experience-year and education-experience fixed effects; and columns 8-9 are estimated in first differences, controlling for the interacted education-year and experience-year effects. We report the corresponding first stage estimates in Table 3. Robust standard errors, clustered by 32 education-experience cells, are in parentheses. We apply the same small-sample corrections as detailed in Table 2. The relevant 95% critical value for the $T$ distribution (with $G - 1 = 31$ degrees of freedom, where $G$ is the number of clusters) is 2.04. *** $p<0.01$, ** $p<0.05$, * $p<0.1$.

This table presents OLS and IV estimates of the native wage equation (33), but this time across broader labor market cells. In columns 1-4, we study 2 broad education groups (college and high-school equivalents) and 8 experience groups; and in columns 5-8, we study the original 4 education groups, but 4 broad experience groups (1-20 and 21-40 years of experience). See Section 7.2 for further details on these groupings. We impose that $\alpha_Z = \sigma_Z = 1$, so the dependent variable collapses to the log natives wage (which we adjust for composition in all specifications), and the cell aggregator on the right hand side collapses to $\log (N + M)$. The fixed effect specifications control for interacted education-year, experience-year and education-experience fixed effects; and the differenced specifications control only for the interacted education-year and experience-year effects. We report the corresponding first stage estimates in Appendix Table A4. Robust standard errors, clustered by 16 education-experience cells, are in parentheses. We apply the same small-sample corrections as detailed in Table 2. The relevant 95% critical value for the $T$ distribution (with $G - 1 = 15$ degrees of freedom, where $G$ is the number of clusters) is 2.13. *** $p<0.01$, ** $p<0.05$, * $p<0.1$.

This table presents OLS and IV estimates of the native wage equation (33), but this time accounting for heterogeneous effects. We study differential effects of migrant share among the college-educated (i.e. some college or college graduate) and older workers (20+ years of experience). We impose that $\alpha_Z = \sigma_Z = 1$, so the dependent variable collapses to the log natives wage (which we adjust for composition in all specifications), and the cell aggregator on the right hand side collapses to $\log (N + M)$. Columns 1-4 control for interacted education-year, experience-year and education-experience fixed effects; and columns 5-8 are estimated in first differences, controlling for the interacted education-year and experience-year effects. We report the corresponding first stage estimates in Appendix Tables A5 and A6. Robust standard errors, clustered by 32 education-experience cells, are in parentheses. We apply the same small-sample corrections as detailed in Table 2. The relevant 95% critical value for the $T$ distribution (with $G - 1 = 31$ degrees of freedom, where $G$ is the number of clusters) is 2.04. *** $p<0.01$, ** $p<0.05$, * $p<0.1$.

Observations: 224 224 192 192

This table presents OLS and IV estimates of the native wage equation (33), but this time, accounting separately for the effect of the new migrant share \(\frac{M_{\text{new}}}{N + M}\) (i.e. up to ten years in the US) and the old migrant share \(\frac{M_{\text{old}}}{N + M}\) (more than ten years). We impose that \(\alpha_Z = \sigma_Z = 1\), so the dependent variable collapses to the log natives wage (which we adjust for composition in all specifications), and the cell aggregator on the right hand side collapses to \(\log (N + M)\). Columns 1-2 control for interacted education-year, experience-year and education-experience fixed effects; and columns 3-4 are estimated in first differences, controlling for the interacted education-year and experience-year effects. We report the corresponding first stage estimates in Appendix Table A7. Robust standard errors, clustered by 32 education-experience cells, are in parentheses. We apply the same small-sample corrections as detailed in Table 2. The relevant 95% critical value for the \(T\) distribution (with \(G - 1 = 31\) degrees of freedom, where \(G\) is the number of clusters) is 2.04. *** \(p<0.01\), ** \(p<0.05\), * \(p<0.1\).

</tbody>
</table>

Panel A reports OLS and IV estimates of native employment rate elasticities, based on the empirical specification in (34). The dependent variable is the mean log of annual hours of natives in each labor market cell (excluding enrolled students), and the regressor of interest is the composition-adjusted native wage. Panel B repeats the exercise for migrants, replacing the employment and wage variables with migrant equivalents. In columns 2-4 and 6-8, we adjust employment rates for changes in demographic composition, following the procedure outlined in Section 7.5. In the ‘IV1’ specification, we instrument the wage variable with predicted log total employment (in the labor market cell) and the predicted migrant share; and in the ‘IV2’ specification, we use the predicted migrant share alone. First stage estimates are reported in Panels C and D. The fixed effect specifications control for interacted education-year, experience-year and education-experience fixed effects; and the differenced specifications control only for the interacted education-year and experience-year effects. Robust standard errors, clustered by 32 education-experience cells, are in parentheses. We apply the same small-sample corrections as detailed in Table 2. The relevant 95% critical value for the $T$ distribution (with $G - 1 = 31$ degrees of freedom, where $G$ is the number of clusters) is 2.04. *** p<0.01, ** p<0.05, * p<0.1.

Observations 224 224 224 224 192 192 192 192

In this table, we study the robustness of our IV estimates of the native wage equation (33) to the wage definition and choice of weighting. Throughout, the right hand side is identical to columns 7 and 9 of Panel B of Table 4, and we also use the same instruments. Odd columns estimate the impact on the wages of native men, and even columns on those of native women. Columns 1-2 and 5-6 study weekly wages of full-time workers (as in the main text), and the remaining columns hourly wages of all workers. All wage variables are adjusted for demographic composition, in line with the method described in Section 4.2. The estimates in Panel A are unweighted (as in Table 4); while in Panel B, we weight observations by total cell employment. Robust standard errors, clustered by 32 education-experience cells, are in parentheses. We apply the same small-sample corrections as detailed in Table 2. The relevant 95% critical value for the \(T\) distribution (with \(G - 1 = 31\) degrees of freedom, where \(G\) is the number of clusters) is 2.13. *** p<0.01, ** p<0.05, * p<0.1.

This table replicates the first and second stage estimates of the native wage equation (33) in Tables 3 and 4, but using an alternative instrument for migrant share. In the main text, our two instruments are \(\log (N + M)\) and \(M \times 10^{-9}\); but here, we replace \(M \times 10^{-9}\) with the predicted migrant employment level, which we have scaled to make the coefficients visible. Columns 1-4 are otherwise identical to columns 3-6 in Table 3, and columns 5-6 are otherwise identical to columns 7 and 9 in Panel B of Table 4. See the notes under Tables 3 and 4 for additional details. *** \(p<0.01\), ** \(p<0.05\), * \(p<0.1\).

This table presents first stage estimates for the native wage equation (33), but this time across broader labor market cells. These estimates correspond to the IV specifications in Table 5. In columns 1-4, we study 2 broad education groups (college and high school equivalents) and 8 experience groups; and in columns 5-8, we study the original 4 education groups, but 4 broad experience groups (1-20 and 21-40 years of experience). See Section 7.2 for further details on these groupings. We impose that \(\alpha_Z = \sigma_Z = 1\), so the dependent variable collapses to the log natives wage (which we adjust for composition in all specifications), and the cell aggregator on the right hand side collapses to \(\log (N + M)\). The fixed effect specifications control for interacted education-year, experience-year and education-experience fixed effects; and the differenced specifications control only for the interacted education-year and experience-year effects. Sanderson-Windmeijer F-statistics account for multiple endogenous variables. Robust standard errors, clustered by 16 education-experience cells, are in parentheses. We apply the same small-sample corrections as detailed in Table 2. The relevant 95% critical value for the \(T\) distribution (with \(G - 1 = 15\) degrees of freedom, where \(G\) is the number of clusters) is 2.13. *** \(p<0.01\), ** \(p<0.05\), * \(p<0.1\).

This table presents first stage estimates for the native wage equation (33), but this time accounting separately for the effect of the new migrant share \(\frac{M_{\text{new}}}{N + M}\) (i.e. up to ten years in the US) and the old migrant share \(\frac{M_{\text{old}}}{N + M}\) (more than ten years). These estimates correspond to the IV specifications of Table 7. We impose that \(\alpha_Z = \sigma_Z = 1\), so the dependent variable collapses to the log natives wage (which we adjust for composition in all specifications), and the cell aggregator on the right hand side collapses to log \((N + M)\). As always, we construct corresponding instruments by applying the same functional forms over the predicted native employment and (in this case) new and old migrant employment separately. Columns 1-3 control for interacted education-year, experience-year and education-experience fixed effects; and columns 4-6 are estimated in first differences, controlling for the interacted education-year and experience-year effects. Sanderson-Windmeijer F-statistics account for multiple endogenous variables. Robust standard errors, clustered by 32 education-experience cells, are in parentheses. We apply the same small-sample corrections as detailed in Table 2. The relevant 95% critical value for the \(T\) distribution (with \(G - 1 = 31\) degrees of freedom, where \(G\) is the number of clusters) is 2.04. *** \(p<0.01\), ** \(p<0.05\), * \(p<0.1\).
In this table, we report IV estimates of the response $\phi_{1N}$ of the native mark-down to the migrant share, $M_N + M$, for a range of $(\alpha_Z, \sigma_Z)$ values. This is identified as the negative of $\gamma_2$, the coefficient on migrant share, in the native wage equation (33). The estimates for $\alpha_Z = \sigma_Z = 1$ are identical to columns 7 and 9 of Panel B of Table 4. Other plotted values replicate the exercise of these columns, but for different $(\alpha_Z, \sigma_Z)$ values. See the notes accompanying that table for further details.

The shaded areas are 95% confidence intervals on our $\gamma_2$ estimates. We offer more formal regression tables for a selection of $(\alpha_Z, \sigma_Z)$ values in Appendix Table A1.
This figure graphically illustrates the OLS and IV effects of migrant employment share, $\frac{M}{MN} + M$, on native composition-adjusted wages, based on columns 4, 7, 8 and 9 of Panel B in Table 4. For the OLS plot, we partial out the effect of the controls (i.e., log total employment and the various fixed effects) from both the composition-adjusted log native wage (on the y-axis) and the migrant employment share (on the x-axis). For IV, we first replace both (i) the log total employment and (ii) the migrant employment share with their linear projections on the instruments and fixed effects; and we then follow the same procedure as for OLS. In the fixed effect specifications, we control for interacted education-year, experience-year and education-experience fixed effects; and in first differences, we control for the interacted education-year and experience-year effects only.
Figure A1: Native and migrant mark-down responses, \( \phi_{1N} \) and \( \phi_{1M} \), to \( \log M_N \)

In this table, we report IV estimates of the native and migrant mark-down responses, \( \phi_{1N} \) and \( \phi_{1M} \), to the log relative migrant supply, \( \log M_N \), for a range of \((\alpha_Z, \sigma_Z)\) values. The native response is identified as the negative of \( \gamma_2 \) in the native wage equation (33). The migrant responses are identified as \( \phi_{1N} + \Delta \phi_1 \), where \( \Delta \phi_1 = -(1 - \sigma + \beta_1) \), and where \( \beta_1 \) is estimated using the relative wage equation (30). We rely on our \( \beta_1 \) estimate of -0.039 from column 5 of Table 2. In the fixed effect (FE) specifications, we control for interacted education-year, experience-year and education-experience fixed effects in the native wage equations; and in first differences (FD), we control for the interacted education-year and experience-year effects only. Estimates are clustered by the 32 education-experience cells. The shaded areas are 95% confidence intervals on our \( \gamma_2 \) estimates. The relevant 95% critical value for the \( T \) distribution (with \( G - 1 = 31 \) degrees of freedom, where \( G \) is the number of clusters) is 2.04. For the native response \( \phi_{1N} \), the standard errors are those on our \( \gamma_2 \) estimates from equation (33). For the migrant response \( \phi_{1M} \), we compute the standard errors as \( \sqrt{[se(\gamma_2)]^2 + [se(\beta_1)]^2} \), where \( se \) are the standard errors on the \( \gamma_2 \) and \( \beta_1 \) estimates respectively.
